CHAPTER 95

Lung Injury Following Hematopoietic Cell Transplantation

Kenneth R. Cooke[1] **and Gregory A. Yanik**[2]
[1]Johns Hopkins University School of Medicine, Baltimore, MD, USA
[2]University of Michigan Cancer Center, Ann Arbor, MI, USA

Introduction

Lung injury occurs frequently following hematopoietic cell transplantation (HCT) and significantly contributes to morbidity and mortality in the immediate post-transplant period and in the months and years that follow [1–4]. Historically, approximately half of all pneumonias seen after HCT have been secondary to infection, but the judicious use of broad-spectrum antimicrobial agents has tipped the balance towards non-infectious causes [5]. However, infectious lung injury remains a significant problem, particularly in patients with acute or chronic graft-versus-host disease (GVHD) or poor/delayed immune reconstitution. Non-infectious lung injury can be either acute or chronic depending upon the time of onset after HCT and the tempo of disease progression. Chronic non-infectious lung injury is further subdivided into two types: obstructive and restrictive [6]. Although non-infectious lung injury can be observed following autologous HCT, the allogeneic setting significantly enhances the severity of disease in both the acute and chronic time frames. This chapter reviews the definitions, risk factors, and pathogeneses of lung injury occurring both early and late after allogeneic HCT.

Diagnostic considerations and role of bronchoalveolar lavage

The approach to HCT patients with pulmonary dysfunction is complex as both pulmonary and non-pulmonary causes are possible. Because symptoms of respiratory distress can progress rapidly once established, the timely coordination of care is essential to optimize outcomes (Figure 95.1). A meticulous history and physical examination are paramount and will help dictate which diagnostic tests and possible consultation with experts in the fields of pulmonology, cardiology, nephrology, radiology, and critical care medicine may be necessary. Determination of the severity of respiratory dysfunction, including an assessment of supplemental oxygen requirement, overall fluid balance, renal function, and cardiac output should be followed by radiographic imaging. An initial chest X-ray or computed tomography (CT) scan may identify the presence of lobar, multilobar, or diffuse pulmonary infiltrates. Although such findings may impact the decision-making process, they are non-diagnostic in and of themselves.

In the absence of obvious left-sided heart failure or iatrogenic fluid overload, bronchoscopy with bronchoalveolar lavage (BAL) or surgical lung biopsy should be considered when multilobar or diffuse infiltrates are present in order to distinguish optimally between infectious and non-infectious causes. BAL samples should be sent for a variety of diagnostic tests to determine the presence of community-acquired and/or hospital-acquired opportunistic infections. In addition to bacterial, fungal, and cytologic stains, quantitative cultures, direct fluorescent antibody stains, and centrifugation (shell vial) cultures should be performed. The emergence of a battery of polymerase chain reaction (PCR) assays may also be very useful, particularly when interpreted in the context of other supportive and correlative data. *Pneumocystis jiroveci (carinii)* pneumonia (PJP) may be identified through a number of techniques, including cytologic studies, special stains, or PCR-based assays.

Despite a large number of published reports, the need to complete BAL in HCT recipients with respiratory compromise remains a matter of debate, particularly in those patients who are critically ill. The diagnostic yield from BAL fluid has ranged from 31 to 67% [7]. Patients are often referred for BAL after several days of symptoms, and often after empiric antibiotic therapy has been initiated. Unfortunately, this approach provides inadequate coverage in over 40% of patients who ultimately are found to have infection [8], and may limit the diagnostic utility of subsequent bronchoscopic procedures. In a large retrospective study of 598 patients who underwent BAL within the first 100 days after HCT at the M.D. Anderson Cancer Center, the overall diagnostic yield of BAL was 55%, with the yield 2.5 times greater amongst patients in which a BAL was performed within the initial 4 days of clinical presentation. In addition, pneumonia-associated deaths were three times higher (18% versus 6%) in those patients undergoing bronchoscopy at least 4 days after onset of clinical symptoms [9]. Yanik et al. examined 444 BAL procedures completed on 300 patients (20% of all patients) who received HCT at the University of Michigan from 2001 to 2007 [10]. It was found that 13% of BAL specimens collected in the first 30 days of HCT were positive for infection, which increased to 33% between days 31 and 100. Hence, although the majority of BAL fluid samples collected within the first 100 days may be negative, a significant number of individuals had evidence for infection. To this end, BAL data resulted in changes in medical management in approximately 60% of cases, and modifications in antimicrobial therapy in just under half. Since the medical management for non-infectious and infectious pneumonia is quite different, making the appropriate diagnosis is important. In both the M.D. Anderson and

University of Michigan series, the bronchoscopy-related complication rates were less than 2.0%.

Infectious lung injury

Major factors contributing to the development of infectious lung injury following HCT include the suppression of laryngeal or cough reflexes, impaired removal of respiratory secretions due to decreased mucociliary clearance or airway obstruction, and dysfunctional or absent humoral and cellular defense mechanisms. Quantitative and/or qualitative defects in neutrophil or lymphocyte function can allow non-pathogenic organisms ultimately to become both invasive and pathogenic. A fine balance exists between those organisms which become true pathogens and those which remain commensurate, with the scales capable of tipping in either direction based on the quantity of inoculum received and the host-defense factors outlined above. Infectious pneumonias may be subdivided into those associated with either interstitial or parenchymal involvement. Common pathogens that cause interstitial pneumonitis include community-acquired respiratory viruses [e.g., parainfluenza, respiratory syncytial virus (RSV), influenza, metapneumonia], mycoplasma, and opportunistic pathogens such a *P. jiroveci*, whereas bacterial and fungal pathogens are more frequently associated with parenchymal changes (Table 95.1). While advancements in molecular techniques and the development of improved anti-microbial therapies have helped improve early detection and successful management of pneumonia caused by several opportunistic organisms, infectious lung injury remains a significant problem following HCT particularly in patients with GVHD or delayed immune reconstitution. The epidemiology, clinical spectrum of disease and overall impact on HCT outcomes of opportunistic bacterial, fungal and viral (including CMV) respiratory infections are described in Chapters 82, 85, and 92, respectively.

Table 95.1 Common infectious pathogens of diffuse interstitial pneumonia

Viral:
- Cytomegalovirus (CMV)
- Adenovirus
- Human herpes virus 6 (HHV-6)
- Varicella virus
- Respiratory syncytial virus
- Parainfluenza type 1 and 2
- Influenza A and B
- Rhinovirus
- Meta-pneumovirus

Protozoan:
- *Pneumocystis jirovecii* pneumonia (PCP)
- *Toxoplasma gondii*
- *Mycoplasma*
- *Chlamydia*

Mycobacterial infections:
- Miliary tuberculosis

Non-infectious, acute lung injury

Non-infectious lung injury following HCT may be mediated by either immune or non-immune mechanisms. Common alloimmune lung complications include idiopathic pneumonia syndrome (IPS), transfusion-related lung injury (TRALI), diffuse alveolar hemorrhage (DAH), and peri-engraftment respiratory distress syndrome (PERDS), with both DAH and PERDS existing as a subset of IPS. Non-alloimmune conditions may include the direct cytotoxic effects of HCT conditioning regimens, cardiogenic dysfunction, and iatrogenic causes of pulmonary edema.

Chemotherapy-associated pneumonitis

Initially described in the 1970s, chemotherapy-associated pulmonary toxicity has been reported in association with multiple chemotherapeutic agents, including bis(chloroethyl)nitrosourea (BCNU), busulfan, and melphalan. BCNU-related lung injury typically presents within the first 3 months following HCT with a non-productive cough and increasing dyspnea in the context of rapidly progressing, bilateral, interstitial infiltrates radiographically [11]. Pulmonary function testing reveals restrictive lung disease with diminished forced vital capacity (FVC) and total lung capacity (TLC) measurements. Independent risk factors for BCNU pneumonitis include an absolute BCNU dose over 1000 mg (even when less than 450 mg/m^2), younger donor age (<54 years), and prior mediastinal irradiation [12]. Treatment with pulsed doses of corticosteroids early in the clinical course significantly decreases the morbidity and mortality; if untreated, or recognized late in its course, severe pulmonary fibrosis may develop.

Delayed pulmonary toxicity syndrome (DPTS) was frequently reported in autologous patients receiving chemotherapy with regimens that contain BCNU, cyclophosphamide, and cisplatin – typically in the setting of metastatic breast cancer. The incidence of DPTS was as high as 29–64% with a median time to onset of 45 days. Treatment with corticosteroids (1 mg/kg/day) leads to resolution in up to 92% of cases, and high-dose inhaled corticosteroid prophylaxis may also be beneficial [13]. Finally, busulfan, in combination with cyclophosphamide or melphalan, has also been implicated in post-transplant lung dysfunction. While pharmacokinetic targeting has minimized busulfan-related toxicity, an increased incidence of pulmonary complications has been observed when local lung radiotherapy is delivered prior to busulfan administration [14].

Transfusion-related acute lung injury (TRALI)

TRALI is the leading cause of mortality following infusions of plasma-containing blood products, and occurs following 1:1000 to 1:5000 transfusions [15,16]. All plasma-containing blood products, including whole blood, packed red blood cells, fresh frozen plasma, platelets, cryoprecipitate, granulocytes, immunoglobulin infusions, and stem-cell products have been linked to the development of TRALI, with albumin the sole exception. The diagnosis is suspected with acute onset of dyspnea and respiratory distress typically occurring 1–6 hours after transfusion. Chest radiographs reveal diffuse pulmonary infiltrates reflecting edema from increased pulmonary vascular permeability. Pathologically, neutrophilic infiltrates and over-expression of neutrophil-related cytokines and chemokines have been linked to TRALI. With associated mortality rates approximating 5–10%, TRALI accounts for nearly half of all transfusion-related deaths. Treatment is generally supportive. Discontinuation of the blood products and initiation of respiratory support result in recovery within 3–4 days in the majority of patients. TRALI is a capillary leak syndrome and not an issue with fluid overload, hence the use of steroids and forced diuresis should be instituted with caution to prevent hypovolemia. In over 70% of cases, antibodies directed against human leukocyte antigen (HLA) class I or II epitopes on recipient hematopoietic cells have been identified as the primary cause of the TRALI event, but in rare cases the antibody may be present in the recipient's plasma, and directed against transfused donor leukocytes [17].

Idiopathic pneumonia syndrome (IPS): definition, clinical course, and spectrum of disease

IPS is defined as widespread alveolar injury following HCT that occurs in the absence of an active lower respiratory tract infection or cardiogenic causes [4,18]. As shown in Table 95.2, diagnostic criteria of IPS include signs and symptoms of pneumonia, non-lobar radiographic infiltrates, abnormal pulmonary function, and the absence of infectious organisms as determined by BAL or lung biopsy [2,4,18]. A variety of histopathologic findings have been associated with IPS, and interstitial pneumonitis (a term historically used interchangeably with IPS) is the most frequently reported pattern [19]. The incidence of IPS in the first 120 days after allogeneic HCT following high-dose conditioning ranges between 3 and 15%, depending on the donor type (related versus unrelated) and degree of antigenic mismatch between donor and recipient [2–4,18]. The median time of onset for IPS was initially reported to be 6–7 weeks (range 14–90 days) after HCT [18], and mortality rates ranged from 50 to 80% overall, with more than 95% mortality for patients requiring mechanical ventilation [4]. A retrospective study in Seattle showed a lower incidence and earlier onset of IPS than previously reported, but the typical clinical course involving the rapid onset of respiratory failure leading to death remained unchanged [3]. Long-term survival in pediatric patients is also poor, with transplant-related mortality (TRM) significantly higher than in non-affected patients (5-year TRM: 52% vs. 13%, $p = 0.001$) [20]. Recent studies suggest that the history of prior viral respiratory tract infections, use of reduced-intensity conditioning (RIC) regimens, and umbilical cord blood as a stem-cell source may impact the frequency, time of onset, and overall mortality of IPS [4].

The clinical spectrum of IPS encompasses several forms of pulmonary toxicity (Figure 95.2, Table 95.3). In one small subset of patients, acute pulmonary hemorrhage or hemorrhagic alveolitis occurs. DAH generally develops in the immediate post-HCT period and is characterized by progressive shortness of breath, cough, and

Table 95.2 Definition of idiopathic pneumonia syndrome

I. Evidence of widespread alveolar injury:
  a. Multilobar infiltrates on routine chest radiographs or CT
  b. Symptoms and signs of pneumonia (cough, dyspnea, tachypnea, rales)
  c. Evidence of abnormal pulmonary physiology
    1. Increased alveolar to arterial oxygen difference
    2. New or increased restrictive pulmonary function test abnormality
II. Absence of active lower respiratory tract infection based upon:
  a. Bronchoalveolar lavage negative for significant bacterial pathogens including acid-fast bacilli, *Nocardia* and *Legionella* species
  b. Bronchoalveolar lavage negative for pathogenic non-bacterial microorganisms:
    1. Routine culture for viruses and fungi
    2. Shell vial culture for CMV and respiratory syncytial virus (RSV)
    3. Cytology for CMV inclusions, fungi and *Pneumocystis jiroveci (carinii)*
    4. Direct fluorescence staining with antibodies against CMV, RSV, HSV, VZV, influenza virus, parainfluenza virus, adenovirus, and other organisms
  c. Other organisms/tests also to consider:
    1. Polymerase chain reaction (PCR) for human metapneumovirus (HMP), rhinovirus, coronavirus, and HHV-6
    2. PCR for *Chlamydia*, *Mycoplasma*, and *Aspergillus* species
    3. Serum galactomannan ELISA for *Aspergillus* species
  d. Transbronchial biopsy if condition of the patient permits
III. Absence of cardiac dysfunction, acute renal failure, or iatrogenic fluid overload as etiology for pulmonary symptomatology

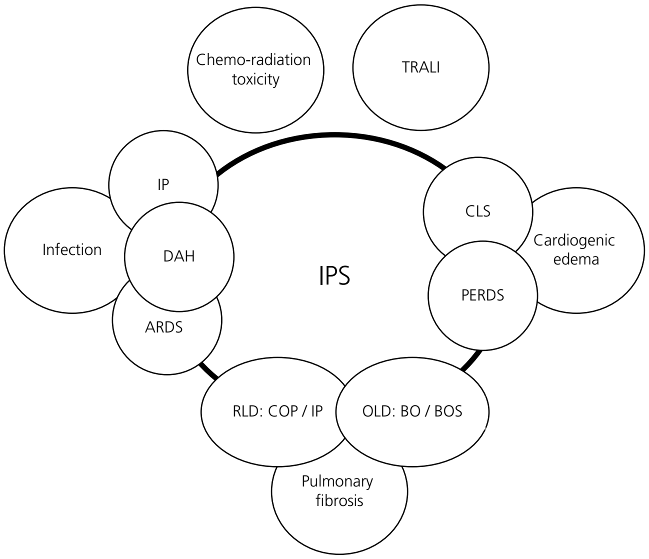

Figure 95.2 Clinical spectrum of IPS. The clinical spectrum of IPS includes a variety of descriptive forms of lung injury that may share clinical features with toxicity incurred by chemo-radiotherapy, cardiogenic edema, pulmonary fibrosis, infection, and transfusion-associated lung injury (TRALI). ARDS, acute respiratory distress syndrome; BO, bronchiolitis obliterans; BOS, bronchiolitis obliterans syndrome; COP, cryptogenic organizing pneumonia; CLS, capillary leak syndrome; DAH, diffuse alveolar hemorrhage; IP, interstitial pneumonitis; OLD, obstructive lung disease; PERDS, peri-engraftment respiratory distress syndrome; RLD, restrictive lung disease.

Table 95.3 The spectrum of non-cardiogenic, pulmonary toxicity defined by IPS

Interstitial pneumonitis (IP):
- Clinical symptoms: fever, cough, dyspnea, hypoxemia
- Onset: within first 100 days post-transplant
- Etiology: infectious (i.e. CMV, PCP) or non-infectious factors (chemotoxicity: BCNU, bleomycin, busulfan, methotrexate)
- Radiographic findings: bilateral interstitial infiltrates

Diffuse alveolar hemorrhage (DAH):
- Clinical symptoms: progressive dyspnea, cough, rare hemoptysis
- Key finding: progressively bloodier aliquots of lavage fluid
- Onset: early, within first 100 days post-transplant.
- Radiographic findings: diffuse infiltrates, central appearance initially noted
- Histology: diffuse alveolar damage with alveolar hemorrhage

Peri-engraftment respiratory distress syndrome (PERDS):
- Clinical symptoms: fever, dyspnea, hypoxemia
- Onset: very early, within 5–7 days of engraftment, classically after autologous SCT
- Radiographic findings: bilateral interstitial infiltrates

Non-cardiogenic capillary leak syndrome (CLS):
- Clinical symptoms: dyspnea, cough, weight gain, edema
- Onset: early, within first 30 days post-transplant
- Radiographic findings: bilateral peri-hilar infiltrates, pulmonary edema, pleural effusions

Cryptogenic organizing pneumonia (COP):
- Clinical symptoms: fever, dry cough, dyspnea
- Onset: 2–12 months post-transplant
- Radiographic findings: patchy airspace disease, ground glass appearance, nodular opacities
- Histology: peri-bronchiolar infiltration and fibrosis and the presence of intraluminal granulation tissue

Bronchiolitis obliterans (BO):
- Clinical symptoms: cough, dyspnea, wheezing, lack of fever
- Pulmonary function testing: obstructive findings (diminished FEV_1 or FEV_1/FVC)
- Onset: 3–24 months post transplant
- Radiographic findings: hyperinflation, otherwise routinely normal
- CT: bronchiectasis, centrilobular nodules, septal lines, ground-glass appearance
- Histology: lymphocytic bronchitis, bronchiolar inflammation with luminal obliteration

Table 95.4 Risk factors for IPS

Graft-versus-host disease prophylaxis (methotrexate)
Acute graft-versus-host disease
Increasing recipient age
Total body irradiation (≥1200 cGy)
Myeloablative conditioning
Decreased pre-transplant performance status
Longer duration from diagnosis to transplant
Transplantation for malignancy other than leukemia
HLA disparity (donor: recipient)

hypoxemia, with or without fever [21]. The definition of DAH requires the demonstration of progressively bloodier aliquots of BAL fluid, but frank hemoptysis is rare. Mortality is high despite aggressive treatment with high-dose steroids, and death usually occurs within weeks of diagnosis [21]. Some patients with DAH can have microorganisms isolated from blood, BAL fluid, or tracheal aspirate within 1 week of alveolar hemorrhage. Majhail et al. compared patients with DAH and infection-associated alveolar hemorrhage who presented with similar clinical and radiographic findings in the setting of progressively bloodier BAL fluid following allogeneic HCT [22]. Infectious and non-infectious alveolar hemorrhage causes were found to be related but distinct entities with extremely poor outcomes following conventional therapy, including steroids [22]. PERDS also falls within the definition of IPS. PERDS is characterized by fever, dyspnea, and hypoxemia that, by definition, occur within 5–7 days of neutrophil engraftment [23]. PERDS in the autologous setting responds promptly to corticosteroids and is associated with a favorable prognosis [23], whereas response to therapy and overall outcomes are poor after allogeneic HCT [3,4,24,25]. PERDS can be distinguished from chemotherapy-induced lung injury by both time of onset and the implication of engraftment-associated cytokine release and capillary leak as underlying cause for pulmonary inflammation.

Risk factors of IPS

As shown in Table 95.4, risk factors for IPS include conditioning with high-dose total body irradiation (TBI), acute GVHD, older recipient age, high-risk disease status, initial diagnosis of malignancy other than leukemia, and, in some reports, the use of methotrexate for GVHD prophylaxis [4,20,26]. In a meta-analysis, it was found that lung irradiation dose, cyclophosphamide dose, and the addition of busulfan were significantly associated with the development of interstitial pneumonitis, and that lung shielding reduced the incidence of HCT-related IPS [27]. The cumulative incidence of IPS within 120 days of HCT was found to be significantly lower following a non-myeloablative conditioning regimen using a single dose of TBI than observed following conventional conditioning despite greater patient age and a similar incidence of acute GVHD [28]. Once established, however, pulmonary toxicity remains severe and culminated in respiratory failure in the majority of patients. These findings suggest that the intensity of HCT conditioning contributes to the development of IPS, and are consistent with data generated from preclinical models showing that the lung is sensitive to the combined effects of radiation and alloreactive T cells. The impact that more robust but reduced-intensity regimens and other factors including stem cell source will have on IPS remains to be fully elucidated.

Table 95.5 Categorization of the clinical spectrum of lung injury following HCT

Clinical spectrum of disease as categorized by presumed site of primary tissue injury		
Pulmonary parenchyma	**Vascular endothelium**	**Airway epithelium**
Acute interstitial pneumonitis (AIP)[a]	Peri-engraftment respiratory distress syndrome (PERDS)*	Cryptogenic organizing pneumonia (COP)/bronchiolitis obliterans organizing pneumonia (BOOP)[a]
Adult respiratory distress syndrome (ARDS)[a]	Non-cardiogenic capillary leak syndrome (CLS)[a]	Bronchiolitis obliterans (BO)
BCNU pneumonitis	Diffuse alveolar hemorrhage (DAH)[a]	
Radiation pneumonitis	Pulmonary venocclusive disease (PVOD)	
Delayed pulmonary toxicity syndrome (DPTS)	Transfusion-related acute lung injury (TRALI)	
Post-transplant lymphoproliferative disease (PTLD)	Pulmonary cytolytic thrombi (PCT)	
Eosinophilic pneumonia (EP)	Pulmonary arterial hypertension (PAH)	
Pulmonary alveolar proteinosis (PAP)	Pulmonary thrombo-embolus (PTE)	

[a] Conditions routinely included under the classification of idiopathic pneumonia syndrome (IPS).

Table 95.6 Animal models of IPS

HCT donors	**HCT recipients**	**Mismatch**	**Conditioning**
B10.Br	Cba	Multiple minor Ags	TBI: 1100 cGy
C57bl/6	B10.Br	Complete mismatch	TBI: 750 Cgy ± Cy

Lp/J	C57bl/6	Multiple minor Ags	TBI: 1300 cGy

Ags, antigens; cGy, centigray; Cy, cytoxan; TBI, total body irradiation.

Etiology of IPS

Potential etiologies for IPS include direct toxic effects of HCT conditioning regimens, occult pulmonary infections, and soluble and cellular inflammatory mediators implicated in the development of other forms of pulmonary injury and acute GVHD. Acute GVHD often precedes IPS, suggesting a possible causal relationship between the two disorders [4,29]. Moreover, the consistent association between lung injury and target organ GVHD in experimental models also supports such an etiology [30–33]. However, the lung has not been traditionally recognized as a classic GVHD target organ, and the specific contribution of alloreactive donor T-lymphocytes to IPS remains a topic of considerable debate. Epithelial apoptosis, a finding attributed to T-cell-mediated injury and considered pathognomonic for acute GVHD, is not consistently observed in allogeneic HCT recipients with IPS [19,34]. By contrast, a histologic spectrum of "pulmonary GVHD" ranging from early diffuse alveolar injury to cicatricial BO, a late and irreversible form of lung injury after HCT, has been described [19]. The heterogeneity of pulmonary histopathology is complicated further by the nonspecific changes that occur after mechanical ventilation, the limited frequency with which lung biopsies are completed on HCT recipients, and the quality and quantity of specimens obtained. In an attempt to address this issue, investigators recently categorized the disease entities falling under the umbrella of IPS by the primary anatomic site of cellular damage: the interstitial tissue, vascular endothelium, or airway epithelium (Table 95.5). Although some cases may remain unclassifiable, this approach may focus future lines of investigation on specific pathways of tissue injury and thereby foster the development of therapeutic interventions that can be tailored to distinct subtypes of disease [4].

Animal models of human disease

To define better the pathogenesis of IPS, several rodent models have been developed and used extensively to investigate immunologic mechanisms of injury that contribute to damage to the vascular endothelium and to the alveolar and bronchiolar epithelium (Table 95.6) (reviewed in [4]). These preclinical models have consistently shown that the development of significant, non-infectious lung injury correlates with the presence but not the severity of systemic GVHD [31]. A model using a complete major histocompatibility complex (MHC) mismatched donor–recipient strain combination best reproduces acute, early-onset IPS. In this system, pulmonary toxicity is caused by the influx of host monocytes and donor T cells into the lungs of lethally irradiated mice within the first 2 weeks of HCT [33]. Intensifying the pre-HCT conditioning with cyclophosphamide accelerates the development of IPS, consistent with human data. From a classification standpoint (see Table 95.5), lung injury is characterized by injured type II alveolar epithelial cells, endothelial cells, and increased frequencies of cytotoxic T-lymphocytes and immune cells expressing B7 family costimulatory ligands in the alveolar and interstitial spaces [33]. Lung dysfunction reflects this interstitial and alveolar damage and presents as reduced specific compliance, decreased total lung capacity, and increased wet and dry lung weights. BAL fluid of mice with IPS contains elevated levels of soluble mediators including cytokines, nitrites, lactate dehydrogenase, and total protein, indicative of lung inflammation and pulmonary endothelial damage and leak [35].

Other more clinically relevant murine systems exist wherein donor and host are haploidentical or differ only at multiple minor histocompatibility complex (HC) antigens or isolated MHC class I or class II loci. These systems specifically model IPS that develops during the first 2–3 months after HCT and is characterized by donor leukocyte infiltration into the lung [4]. Regardless of strain combination, two primary, reproducible abnormalities are apparent: a dense mononuclear cell infiltrate around both pulmonary vessels and bronchioles and an acute pneumonitis involving the interstitium and alveolar spaces representing each of the three anatomic categories outlined in Table 95.5 [31,36,37]. When measured, alterations in pulmonary function are associated with lung histopathology, demonstrating that the observed lung inflammation is physiologically relevant [31,33,38]. Despite the presence of endothelial damage, DAH is not regularly seen in preclinical IPS models. The only exception is when mice with severe GVHD are challenged with lipopolysaccharide (LPS). In this scenario, hemorrhage is associated with large increases in BAL fluid levels of neutrophils, tumor necrosis factor-alpha (TNF-α), and LPS [31,36].

The pathogenesis of IPS

The pathophysiology of IPS is complex. Data generated using experimental models described above support a shift away from the current paradigm of acute lung injury after HCT as an idiopathic clinical syndrome and towards a process in which the lung is susceptible to two distinct but interrelated pathways of immune-mediated injury: a T-cell axis and an inflammatory cytokine axis. Collectively, these include aspects of the adaptive and the innate immune responses, synergistic interactions between cells from the lymphoid and myeloid lineages, and the release of soluble inflammatory molecules (Figure 95.3). These distinct but related pathways of inflammation culminate in the recruitment of immune cells to the lung leading to tissue damage and dysfunction.

Soluble inflammatory mediators

Evidence for cytokine activation during the development of IPS has been demonstrated in clinical studies, which have shown increased pulmonary vascular permeability and increases in BAL fluid and serum levels of several cytokines (TNF-α, sTNFR receptors I and II, IL-6) and inflammatory chemokines (IL-8, MCP-1, MIG) that regulate leukocyte recruitment to sites of inflammation [1,25]. A causal role for TNF-α in the development of experimental IPS has been established using strategies that either neutralize its effects [36] or use TNF-α-deficient mice as HCT donors [39]. Neutralization of TNF-α at the time of LPS challenge effectively prevents enhanced pulmonary inflammation – confirming the linkage between LPS and TNF-α in this setting – and reduces the severity of lung injury when implemented during the natural course of disease [36]. Studies using genetically altered mice have shown that IPS is dependent upon donor-derived, rather than host-derived, TNF-α. Although TNF-α from both donor accessory cells (macrophage/monocytes) and T cells contributes significantly to lung injury, the T-cell component predominates [39].

The actions of TNF-α are mediated by two receptors: a 55–60-kDa type I receptor (TNFRI; p55/60; CD120a) and a 75–80-kDa type II receptor (TNFRII; p75/80; CD120b). TNFRI is constitutively expressed, whereas the expression of TNFRII is strongly regulated by various cytokines and other inflammatory stimuli. In one report, the absence of TNFRI was associated with decreased pulmonary edema and improved lung compliance on day 7 of allo-HCT [40]. However, cellular infiltration into the lung and BAL fluid levels of proinflammatory cytokines was actually higher in mice deficient in

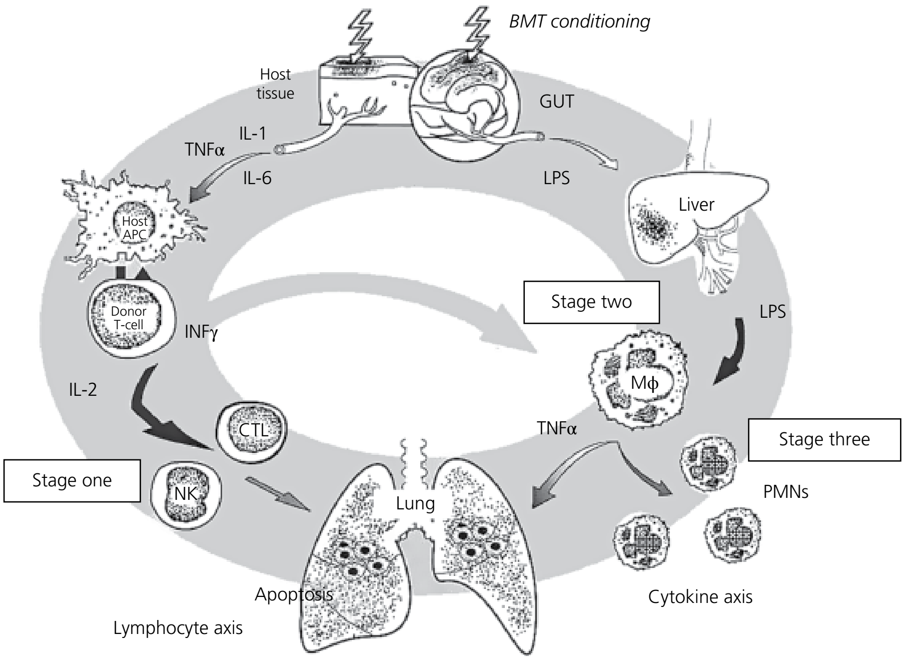

Figure 95.3 Pathophysiology of IPS. Data generated using murine HCT models have been incorporated into a working hypothesis of IPS physiology. This schema postulates that the lung is susceptible to two distinct but inter-related pathways of immune mediated injury that occur along a T-lymphocyte activation axis and a "gut–liver–lung" axis of inflammation. Chemo-radiotherapy of HCT conditioning causes cytokine release that enhances the ability of host antigen-presenting cells to present alloantigens to mature donor T cells and upregulates chemokine expression in the lung. Once engaged, donor T cells become activated and secrete IFN-γ and IL-2. IFN-γ primes donor macrophages (Mφ) and monocytes, whereas IL-2 facilitates T-cell activation and the generation of CXCR3 expressing Th1 lymphocyte effectors that migrate to the lung early after HCT (stage one) in response to inflammatory chemokine gradients and contribute to pulmonary toxicity via Fas/FasL-mediated cell killing. The inflammatory axis focuses on the relationship between the cellular activating effects of LPS and the downstream production of TNF-α as it occurs along a gut–liver–lung axis of inflammation. LPS enters the systemic circulation through gaps in the intestinal mucosa. The ability of systemic endotoxin to reach the alveolar space is related to the consequences of GVHD in other target organs, particularly the liver, which is pivotally located immediately downstream (via the splanchnic circulation) of the intestinal reservoir of Gram-negative bacteria and their toxic byproducts. CCR2 expressing donor macrophages primed by IFN-γ are recruited to the lung (stage two) where they are triggered by LPS to secrete inflammatory cytokines like TNF-α, resulting in enhanced chemokine expression, the recruitment of neutrophils to the lung, and increased tissue damage (stage three).

TNFRI compared with controls. These findings are consistent with a more recent study showing that compared with controls, TNFRII-deficient, allogeneic HCT recipients develop significantly less severe IPS, which is associated with reductions in pulmonary ICAM-1 expression and in leukocyte infiltration into the lungs [41].

The release of inflammatory cytokines, including TNF-α, has been linked to the cellular activating effects of endogenous microbial products such as LPS. Experimental results from established mouse models [42,43] are consistent with clinical observations showing that (1) monocytes upregulate CD14 expression following recruitment to an inflamed lung and show enhanced sensitivity to LPS stimulation [44], and (2) evidence of cytokine activation and components of the LPS activating system (including lipopolysaccharide binding protein and soluble CD14) in the BAL fluid and plasma of patients with IPS [1,25]. Recent plasma proteomic studies revealed striking similarities between the inflammation engendered during IPS in humans and mice and underscored a significant contribution of the acute phase response (TNF-α/IL-6) signaling pathway during disease progression. Moreover, the results identified a set of robust markers predictive for disease progression and response to therapy and suggested that patients whose innate immune response are "hot-wired" to respond to the release of microbial products with high level secretion of TNF-α may be more likely to be protected via strategies that neutralized the inflammatory effects of this protein [45]. Accordingly, strategies that neutralize TNF-α do not completely abrogate lung injury [36,39,46] in the experimental and clinical settings, suggesting that other inflammatory and cellular mechanisms also contribute to the development of IPS. Delivery of chemo-radiotherapy during HCT conditioning, concurrent presence of iron overload, and lung-infiltrating inflammatory cells all contribute to the release of molecules that contribute to the generation of both oxidative and nitrosative stress. Because of its oxygen-rich environment, the lung is particularly sensitive to the effects of these conditions, and experimental and clinical data suggest that amelioration of oxidative stress may be an effective strategy to reduce the severity of pulmonary toxicity during IPS (reviewed in [4]).

Pulmonary surfactant

Pulmonary surfactant is produced by alveolar type II cells and is composed of a complex mixture of lipids and at least four surfactant proteins (SPs). By reducing surface tension, surfactant decreases the work of breathing, allows alveoli to remain open at end expiration, and keeps alveoli dry. SP-A and SP-D also have a major role in host defense and in regulating immune responses in the lung [47]. Reduced production or dysfunction of SPs contributes to the clinical picture of hypoxemia, progressive dyspnea, and pulmonary edema that is associated with IPS. Mice lacking SP-A or SP-D exhibit exaggerated allogeneic T-cell-dependent inflammation that is associated with enhanced markers of lung injury, and intratracheal instillation of human SP-A attenuates the manifestations of IPS in this setting [48]. In humans, low pre-HCT serum levels of SP-D may predispose individuals to enhanced inflammatory responses following exposure to conditioning regimens and allogeneic immune responses and have been shown to (1) represent a risk factor for the development of IPS and bronchiolitis obliterans [49], (2) associate with certain polymorphisms in the human SP-D gene [50], and (3) be a valuable biomarker in acute lung injury that can predict outcome [51]. Despite its overwhelming therapeutic success in premature infants, results of surfactant replacement trials during acute lung injury after HCT in children and adults have been variable [52]. A phase III study is under way in pediatric HCT recipients to determine the efficacy of novel surfactant preparations that closely resemble natural surfactant.

Donor immune cells

The role of alloreactive donor T cells in the pathogenesis of IPS remains a topic of considerable debate. The importance of lymphocytes to lung injury after experimental HCT has also been shown by several groups [30–33,39]. Donor T cells are critical to the early proinflammatory events associated with lung injury that develops within the first week of HCT across MHC antigens, whereas in minor H antigen mismatch systems, donor lymphocytes continue to contribute to physiologically significant lung injury at later time points [32,33]. Donor cytotoxic T-lymphocytes (CTLs) can contribute to lung injury via three primary cytolytic mechanisms: the perforin–granzyme, Fas/Fas ligand (FasL), or TNF-α pathways. Each pathway has been shown to contribute to lung injury in non-HCT models. Furthermore, cytolytic T cells expressing granzyme B are present in the lungs of mice after allogeneic HCT, and they colocalize with macrophages expressing the costimulatory molecules B7.1/CD80 and B7.2/CD86 [33]. Alloantigen-specific killing by donor T cells using both the perforin and Fas/FasL pathways has also been identified in the lung after HCT. Pulmonary CTL activity is present as early as week 2 after transplant [53]. Whereas both FasL- and TNF-α-mediated cytolytic pathways are utilized during the evolution of IPS caused by Th1 ($CD4^+$) T cells, Tc1 ($CD8^+$) T cells use TNF-α exclusively.

Some studies have challenged the role of Th1/Tc1 effectors in the development of IPS and paradoxically showed that pulmonary inflammation is accelerated when interferon-gamma (IFN-γ) signaling is blocked [54]. These results were later independently confirmed and extended to show that IFN-γ negatively regulates the expansion of $Th17^+CD4^+$ T cells in the lungs during IPS [55]. In vitro differentiated Th17 cells also mediated severe pulmonary pathology in a mouse GVHD model [56] and the role of Th17 cells in tissue inflammation is currently an area of intense study [57]. These findings notwithstanding, robust lung inflammation has been reproducibly observed in several models when receptor–ligand interactions are completely intact, a scenario that is likely more applicable to the human disease state.

Experimental data suggest that synergistic interactions between cells from the lymphoid and myeloid lineage are critical to the development of lung inflammation after allogeneic HCT. Donor macrophages are recruited to the lung within the first several weeks after experimental HCT [58], are a significant, albeit not the primary, source of TNF-α [39], and their responsiveness to LPS stimulation correlates with the severity of IPS [42,43]. Experimental results obtained using CD14-deficient donors are consistent with reports showing that when recruited to an inflamed lung, monocytes upregulate CD14 expression and show enhanced sensitivity to LPS stimulation [44], and with the clinical observations made in the BAL fluid of patients with IPS [1,25]. Polymorphonuclear cells are a major component of the mixed inflammatory infiltrates, and increases in TNF-α seen in the lungs of animals with IPS [31,36], and their appearance in the bloodstream, are often temporarily associated with the onset of lung inflammation in humans [25]. Neutrophil products such as elastase, myeloperoxidase, metalloproteinases, and oxidants are abundant in the BAL fluid of patients with adult respiratory distress syndrome (ARDS) and during lung allograft rejection and are believed to contribute to the endothelial and epithelial damage that occurs in each setting [59,60].

Mechanisms of leukocyte recruitment to the lung during IPS

White blood cell (WBC) migration to sites of inflammation has been studied extensively and involves interactions between leukocytes and endothelial cells that are mediated by adhesion molecules, chemokines, and their receptors [61]. Mouse models have shown that the mRNA expression of intracellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin are increased in the lungs of mice after allogeneic HCT [62], and the severity of IPS is dramatically reduced when ICAM-1-deficient mice are used as HCT recipients of either MHC-matched or -mismatched allogeneic donor cells [37,63]. Investigators have also begun to explore the role of chemokine receptor–ligand interactions in IPS, which can be conceptualized in three distinct stages (reviewed in [4,64]). This hypothesis stipulates that the migration of each leukocyte subset controls the recruitment of the next wave of effectors. In this paradigm, the recruitment of Th1/Tc1 effectors [65–68] initiates the cascade, and plays an active role in regulating the inflammation engendered during the evolution of IPS [39,58].

Targets of inflammation and injury during IPS

Although yet to be definitively established, it is conceivable that pulmonary endothelial and epithelial cells can serve as targets for direct alloimmune-mediated damage. Endothelial cell (EC) damage can be induced by transfer of allogeneic lymphocytes to immunodeficient mice [69] and has been implicated as a direct contributor to the development of several complications, including GVHD, sinusoidal obstruction syndrome, and thrombotic microangiopathy [70]. Evidence for EC injury and leak, as demonstrated by pulmonary edema, enhanced total protein levels in BAL fluid, and increased wet to dry lung weight ratios, are also observed after clinical and experimental IPS [25,33]. In preclinical models, EC apoptosis coincides with the onset of pulmonary pathology, is associated with elevations in BAL fluid TNF-α levels, and is accompanied by evidence for EC activation as measured by enhanced mRNA expression of adhesion molecules [62]. Neutralization of TNF-α early after allogeneic HCT significantly reduces EC apoptosis and lung histopathology observed in mice [62]. TNF-α may therefore function as both an effector and a facilitator of lung injury by contributing directly to EC injury and death, and by regulating the chemokine milieu in the lung during the early stages of IPS.

By contrast, epithelial apoptosis, generally ascribed to T-cell-mediated injury and considered pathognomonic for acute GVHD in other target tissues, has not been consistently observed in allogeneic HCT recipients with lung injury. The unique aspects of epithelial anatomy in the lung may help explain this discrepancy. Since there is no stratification or layering of pulmonary epithelial cells as in the skin or intestine, identification of epithelial cell apoptosis by histologic criteria can be more challenging. Experimental studies have, however, provided evidence for epithelial injury during IPS. Panoskaltsis-Mortari et al. demonstrated that IPS was associated with injured alveolar type II cells and increased frequencies of cytotoxic T-lymphocytes in a model of early-onset IPS [33]. The same group later showed that keratinocyte growth factor, a mediator of epithelial cell proliferation and a growth factor for type II pneumocytes, diminished IPS injury by damping the immune response to chemo-radiotherapy and by accelerating repair of the damaged tissue, specifically alveolar type II epithelial cells [71]. Finally, a new murine model of bronchiolitis obliterans following allogeneic HCT revealed that bronchiolar epithelial cells express MHC class II and are surrounded by cells expressing granzyme B prior to the occlusion of the airways [72].

Table 95.7 Treatment options for IPS

Supportive therapy:
- Supplemental oxygen, mechanical ventilation
- Empiric broad-spectrum antimicrobial agents pending culture results
- Management of iatrogenic fluid overload
- Continuous veno-venous hemofiltration (CVVH)

Immunosuppressive therapy:
- Corticosteroids (2 mg/kg/day)
- Investigational: cytokine inhibitors, including anti-TNF agents

The diagnostic and therapeutic approach to patients with IPS

As discussed earlier in the section Diagnostic considerations and role of bronchoalveolar lavage, and outlined in Figure 95.1, the approach to HCT patients with acute pulmonary dysfunction requires the timely coordination of care across multiple medical subspecialties and a number of diagnostic tests. Once established, current standard treatment regimens for IPS (Table 95.7) include supportive care measures in conjunction with broad-spectrum antimicrobial agents and intravenous corticosteroids [4]. Unfortunately, responses to standard therapy (including high-dose steroids) are limited, and the mortality of patients diagnosed with IPS remains unacceptably high. The early institution of continuous veno-venous hemofiltration may help to improve survival in some pediatric patients [73], but prospective studies addressing the use of this treatment are lacking in the literature. As described above, translational research studies have suggested that neutralization of TNF-α may be a useful option for IPS. In an early phase I/II study, etanercept, a soluble dimeric TNF-α-binding protein, showed promise when given subcutaneously at a dose of 0.4 mg/kg twice weekly (maximum of eight doses) in combination with systemic steroids and empiric antimicrobial therapy to patients with IPS [25]. Ten of 15 patients were able to withdraw completely from supplemental oxygen support and survival at days 28 and 56 (from the first etanercept dose) was significantly improved. In addition, in a retrospective study of 22 patients treated with corticosteroids alone versus 18 patients treated with corticosteroids plus etanercept, overall survival was significantly higher in the etanercept-treated group (88.2% vs. 36.4%, $p = 0.003$) [74].These encouraging results led to the development of two multi-institutional studies that were recently completed. Although etanercept in combination with systemic corticosteroids was associated with high response rates in a phase II study in children with IPS, results were inconclusive in a phase III placebo-controlled trial in adults that closed prematurely secondary to slow accrual [75,76].

Consistent with animal studies, not all patients with IPS respond to etanercept therapy. A recent plasma proteomic study conducted on samples obtained from patients with IPS provided a set of robust markers predictive for disease progression and response to therapy [45]. Indeed, patients prone to respond to alloimmune activation with high-level secretion of TNF-α may be more likely to be protected via strategies that neutralize the inflammatory effects of this protein. In addition, an effort to categorize patients with IPS based on the presumed anatomic site of primary injury and exploiting mechanistic insights gained in the laboratory may avail the use of other promising, non-cross-reactive therapeutic or preventative agents [4]. For example, it is conceivable that approaches to maintain EC integrity may be effective at preventing or treating IPS. The administration of molecules that function as survival factors for ECs has been successful in preventing endothelial damage and mortality from septic shock and radiation injury.

Specifically, keratinocyte growth factors have been shown to be efficacious in reducing epithelial damage and the severity of experimental IPS [71] in addition to protecting pulmonary endothelium from oxygen-induced injury. Similarly, ongoing studies examining the role of surfactant replacement therapy might prove useful in overcoming the effects of epithelial injury and dysfunction on ventilation and oxygenation. Since IPS develops and progresses to respiratory failure despite significant systemic immune suppression, it is possible that novel strategies directed towards inhibiting pathways of leukocyte recruitment to the lung may serve as future adjuncts to standard therapy intended to prevent or treat this serious complication. Such strategies have been successful in early-phase studies for GVHD prevention [77].

Non-infectious, late-onset lung injury: obstructive and restrictive lung disease

Definition, risk factors, and clinical course

Two forms of chronic pulmonary dysfunction are commonly observed in patients surviving more than 100 days after allogeneic HCT: obstructive lung disease (OLD) and restrictive lung disease (RLD). The incidence of both patterns of lung toxicity ranges from 20 to 50%, depending upon donor source and the time interval after HCT [5,6]. In each scenario, collagen deposition and the development of fibrosis either in the interstitial (RLD) or peri-bronchiolar (OLD) space are believed to contribute to the patterns of lung dysfunction displayed on pulmonary function testing. While both forms of pulmonary dysfunction exist as late-onset, non-infectious lung complications following allogeneic HCT, RLD and OLD can be distinguished by a number of clinical parameters (Table 95.8).

Restrictive lung disease

RLD is defined by reductions in forced vital capacity (FVC), total lung capacity (TLC), and diffusion capacity of the lung for carbon monoxide (DLCO) as measured by standard pulmonary function tests (PFTs). In restrictive disease, the ratio of the forced expiratory volume in 1 second (FEV_1) to FVC (FEV_1/FVC) is maintained near 100% [6,78]. RLD is common after HCT; significant decreases in FVC or TLC are reported at day 100 in nearly half of allogeneic HCT recipients. Although at times transient in nature, a decline in TLC or FVC at 100 days and 1 year after HCT compared with pre-transplant values (even if the absolute values for each measurement remained within the normal range) has been associated with an increase in non-relapse mortality [78]. TBI-containing conditioning regimens and the presence of acute GVHD have been associated with RLD, but a relationship with chronic GVHD has yet to be fully characterized.

Table 95.8 Clinical factors present in OLD versus RLD

Presentation	Obstructive lung disease	Restrictive lung disease
Clinical syndrome	BO	COP
Onset	Late (3–12 months)	Early (within 3 months)
Symptoms	Dyspnea, non-productive cough	Dyspnea, non-productive cough
Physical examination	Wheezing	Rales
PFTs	Obstructive physiology	Restrictive physiology
FEV_1/FVC	Decreased	Normal
TLC	Normal	Decreased
DLco	Decreased	Decreased
CT scan findings	Air trapping Bronchial wall thickening Centrilobular nodule	Patchy consolidation: COP "Ground-glass" opacities
Chronic GVHD	Strong association	Variable, association with COP

BOOP, bronchiolitis obliterans organizing pneumonia; BOS, bronchiolitis obliterans syndrome; COP, cryptogenic organizing pneumonia; CT, computed tomography; DLCO, diffusion capacity of the lung for carbon monoxide; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; GVHD, graft-versus-host disease; OLD, obstructive lung disease; PFTs, pulmonary function tests; RLD, restricted lung disease; TLC, total lung capacity.

Histologic features of RLD after HCT are rarely described in the clinical literature. Although reported in less than 2% of HCT recipients, bronchiolitis obliterans organizing pneumonia (BOOP), also known as cryptogeneic organizing pneumonia (COP), is associated with restrictive (rather than obstructive) changes on PFTs [5,78]. Clinical features resemble idiopathic COP and include dry cough, shortness of breath, and fever, while radiographic findings show diffuse, peripheral, fluffy infiltrates consistent with airspace consolidation [78,79]. In the context of allogeneic HCT, the development of COP is strongly associated with prior acute and chronic GVHD [80]. When possible, the diagnosis of COP should be confirmed on lung biopsy specimens by several signature features: patchy fibrosis, granulation tissue within alveolar spaces, alveolar ducts and respiratory bronchioles, and the absence of infectious organisms. While often the case, the term COP or BOOP should not be used interchangeably with BO to describe a patient with chronic lung dysfunction after HCT. The two disorders differ with respect to histopathology, pulmonary function characteristics, and, most importantly, response to therapy; COP after HCT is quite responsive to corticosteroids, and in other settings may resolve spontaneously, whereas BO is not [5,78].

Obstructive lung disease/bronchiolitis obliterans (BO)

OLD was first recognized as a complication of allogeneic HCT in the mid-1980s and is now a well-documented cause of morbidity and mortality. OLD is characterized by enhanced resistance to airflow on expiration and results from narrowing and injury to smaller airways and bronchioles. The diagnosis of OLD is based primarily on spirometric measurements as demonstrated by decreases in FEV_1 and in FEV_1/FVC [6,78]. Obstructive defects as defined by an FEV1/FVC of <70% have been observed in approximately 15–25% of allogeneic HCT recipients by day 100 and can persist for years [6,78,81]. Lung biopsies from patients with OLD have shown several histopathologic patterns, but BO, which depicts small airway inflammation with fibrinous obliteration of the bronchiolar lumen, remains the most common [6,78] (Figure 95.4a) This variation in histopathology is complicated by the methods used to procure lung tissue; trans-bronchial biopsies rarely include an adequate sampling of distal bronchial structures and therefore such specimens can reveal cellular infiltrates involving larger airways and the interstitium without definitive bronchiolar inflammation. Biopsy-confirmed BO has been used historically to describe "chronic GVHD of the lung" [6]. However, significant airflow obstruction may exist without BO, and in most cases, OLD is diagnosed by PFT findings without histopathologic confirmation. In this context, two clinical phrases are described in the literature. "Air flow obstruction" is defined as a more than a 5% per year decline in percent predicted FEV_1 with the lowest post-transplant FEV_1/FVC ratio less than 0.8 [82]. "Bronchiolitis obliterans syndrome" (BOS) denotes the deterioration of graft function that accompanies chronic lung allograft rejection [83].

The lack of consistent terminology and the variability in diagnostic criteria have contributed to wide variations in the reported incidence of OLD after HCT. Afessa et al. found that OLD was reported

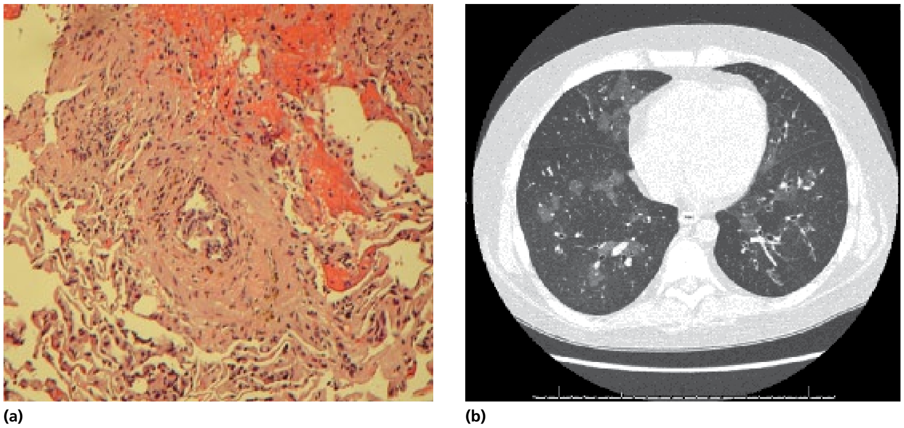

Figure 95.4 Histology and CT of OLD/BO. The cicatricial form of obstructive lung disease/bronchiolitis obliterans includes concentric, periluminal fibrous bands and obliteration of small airways (100×) (a). Expiratory image of chest CT scan shows classic areas of air trapping consistent with inflammation of terminal airways found in obstructive lung disease (b).

in 8.3% of over 2000 allogeneic HCT patients in nine studies and was identified in 6–20% of long-term survivors with chronic GVHD [5]. By contrast, using the definition described above for airflow obstruction, Chien et al. found that new-onset OLD following HCT with high-dose conditioning was more frequent (26% overall and 32% among patients with chronic GVHD) than previous estimates [82]. The onset of OLD ranges from 3 to 18 months after HCT, and is more insidious than IPS [6,78]. Respiratory symptoms include cough, dyspnea, and wheezing, but many patients remain asymptomatic despite showing signs of moderate to severe airway obstruction on PFTs. Chest X-rays are often normal except for signs of hyperinflation, but patchy, diffuse infiltrates can also be present. Likewise, chest CT findings can range from "normal" early in the course of disease to extensive peri-bronchial inflammation and bronchiectasis with significant air trapping at later time points [84] (Figure 95.4b). Non-contrast, high-resolution, chest CT scans are currently the study of choice to evaluate patients with suspected OLD.

Risk factors for OLD include lower pre-transplant FEV_1/FVC, concomitant infections, chronic aspiration, acute and chronic GVHD, HCT using mismatched donors, and high-dose (versus reduced-intensity) conditioning regimens [6,82,85]. Chien et al. examined the impact of age and conditioning intensity and found that the risk for experiencing a yearly decline in FEV_1 in excess of 20% was significantly lower for recipients of RIC than for patients receiving high-dose therapy who were more than 50 years of age [85]. Although donor/host CMV status does not correlate with the development of OLD, previous RSV and adenoviral infections are possible risk factors in the pediatric population [86]. The development of OLD is strongly associated with chronic GVHD, particularly in patients with low serum immunoglobulin G (IgG) levels and with chronic hepatic GVHD [6].

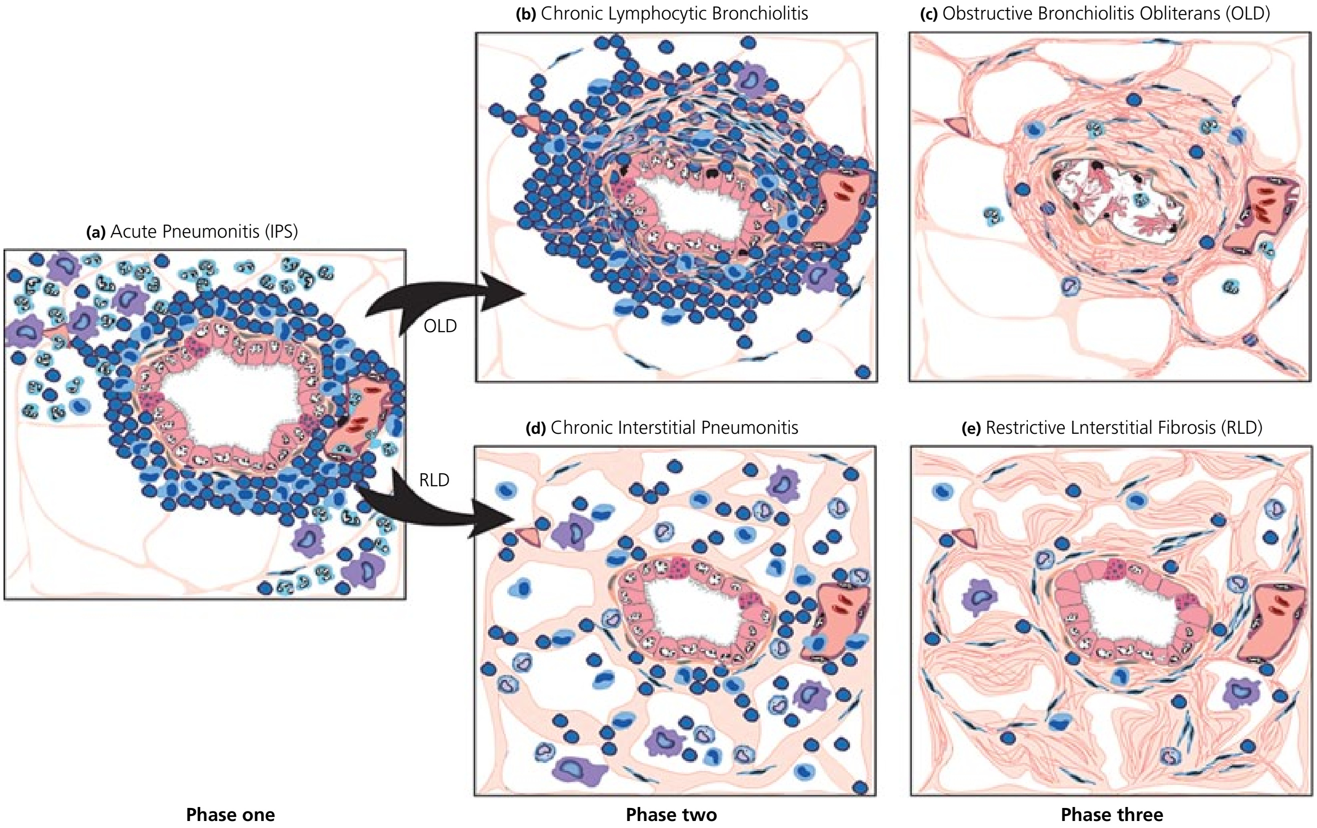
In 2005, the National Institutes of Health (NIH) defined consensus criteria for BO/OLD (Table 95.9) [87]. Using these NIH guidelines, a large retrospective study identified BO/OLD in 5.5% of allogeneic HCT recipients and in 14% of patients who developed chronic GVHD [88]. Pre-transplant FEV_1 and FEV_1/FVC ratios were significantly lower in patients who met the NIH consensus criteria for BOS compared with patients who never met the criteria. Mortality rates were doubled in patients who met the NIH consensus definition compared with those who did not [88]. Once established, the clinical course of OLD can vary from mild to severe with necrotizing bronchiolitis, a rapid decline in FEV_1, and mortality rates of 25–50%. Reports suggest that early detection of disease may be important to improving outcomes. To this end, a decrease of maximum mid-expiratory flow rates (FEV_{25-75}) may represent an earlier indicator of OLD than changes in FEV_1. In addition, rapid rates of airflow decline between 100 days and 1 year after HCT have also been shown to correlate with higher mortality [82]. Finally, pre-transplantation risk scores based solely or in part on pre-HCT lung function may be useful in predicting early respiratory failure and death in patients undergoing allogeneic HCT [89,90]. The clinical scope of OLD/BO along with challenges related to diagnosis, characterization, and approach to treatment have been discussed in detail in several recent comprehensive reviews [81,91–93].

Table 95.9 NIH consensus criteria for BOS

1. FEV_1 <75% predicted, plus FEV_1/FVC ratio <0.7
2. Evidence of air trapping, bronchiectasis or small airway thickening on high-resolution CT (inspiratory and expiratory views). If radiographic findings not evident, then a residual volume (RV) >120% predicted or histologic confirmation of constrictive bronchiolitis
3. Absence of acute respiratory infection. Documentation may include microbiology cultures (bronchoalveolar lavage, sinus aspiration, sputum cultures, or upper respiratory tract viral screen) or radiographic features (CT or chest radiograph) suggestive of infection
4. If BOS is diagnosed by pulmonary function and radiologic testing (without tissue confirmation), then at least one other distinct manifestation of chronic GVHD in a separate organ system must be present

Pathogenesis of chronic lung injury

The pathophysiology of chronic lung injury after HCT is poorly defined, but likely involves an initial insult to lung parenchyma followed by an ongoing dysregulated inflammatory process involving the interplay between recruited immune cells of donor origin and the resident host cells of the pulmonary vascular endothelium and interstitium. A triphasic model of chronic, non-infectious lung injury after HCT has been proposed that involves T-cell activation, leukocyte recruitment, the deposition of collagen, and the development of fibrosis [6,94]. In this model, an allogeneic response to lung epithelial cells initiates a dysregulated reparative response resulting in scarring of either the terminal airways, leading to OLD, or the interstitial space, leading to RLD (Figure 95.5). Precisely what determines the anatomic specificity (peribronchiolar versus interstitial) of chronic lung injury remains



(b) Chronic Lymphocytic Bronchiolitis
(c) Obstructive Bronchiolitis Obliterans (OLD)
(a) Acute Pneumonitis (IPS)
OLD
RLD
(d) Chronic Interstitial Pneumonitis
(e) Restrictive Lnterstitial Fibrosis (RLD)
Phase one
Phase two
Phase three

Figure 95.5 A triphasic model of OLD and RLD following allogeneic HCT. Immune-mediated injury to the lung after allogeneic SCT can be conceptualized in three phases. In phase one, acute lung injury develops as a consequence of an allogeneic immune response and results in the sequential influx of lymphocytes, macrophages and neutrophils into an inflamed pulmonary parenchyma (a). Persistence of an inflammatory signal in the setting of dysregulated repair mechanisms promotes the transition from acute to chronic injury in phase two (b and d). As chronic inflammation proceeds to phase three, lung fibroblasts increase dramatically in number and contribute to the enhanced deposition of collagen and granulation tissue in and around bronchial structures, ultimately resulting in complete obliteration of small airways and fixed OLD (c). If, by contrast, the principal target of early damage is the alveolar epithelium, fibroblast proliferation and intraseptal collagen deposition ultimately result in interstitial fibrosis and RLD (e). (For a color version of this figure, please see the color plate section.)

unclear, and the development of one pattern of chronic lung injury (OLD or RLD) does not necessarily exclude the other [95]. Furthermore, an early, robust inflammatory phase may not be a prerequisite for subsequent fibrosis, a scenario that could explain why some patients with chronic lung dysfunction do not have a clear antecedent history of acute lung inflammation. In this context, pulmonary fibroblasts may represent an important link in the development of both RLD and OLD after allogeneic HCT, and evidence now exists that circulating fibrocytes can be used as a surrogate marker for the severity of BO [96].

The contribution of innate immune dysregulation to the proposed triphasic model is underscored by recent experimental and clinical studies. Compelling evidence for a role of TNF-α in the transition from acute to chronic lung injury is provided by work using transgenic rodents with targeted over-expression of TNF-α in the lungs; early lung histopathology includes a lymphocytic infiltrate similar to that seen in experimental IPS models, whereas the histologic changes associated with more prolonged exposure to TNF-α closely resemble those seen at later time points after HCT. Moreover, in a recent prospective study of TNF-α inhibition for the management of chronic lung injury post-HCT, significant increases in plasma levels of TNFR1 and TNFR2, both surrogate markers for TNF-α, were noted compared with non-HCT controls and with transplant patients who did not develop either BO/OLD or RLD [97]. In addition, two clinical studies demonstrated that genetic variations in both bactericidal/permeability-increasing protein- and nucleotide-binding oligomerization domain containing 2/caspase recruitment domain family member 15 (NOD2/CARD15) influence the risk of airflow obstruction and BO after allogeneic HCT [98,99].

Finally, the recent development of new animal models has underscored the interplay between local innate immunity and non-Th1 cell subsets and the contribution of donor B cell alloantibody production in the development of chronic pulmonary GVHD [72,100,101]. The latter observation was validated mechanistically as infusion of donor cells incapable of making IgG alloantibodies and blockade of germinal center formation abrogated lung fibrosis [140]. Importantly, these experimental findings are supported by the clinical observation that patients with newly diagnosed BO have significantly higher percentages of $CD19^+CD21^{low}$ B cells and levels of B-cell-activating factor (BAFF) in the peripheral blood compared with allogeneic HCT recipients without chronic GVHD [102]. Collectively, genetic approaches along with the scientific exploitation of relevant animal models for BO [72] may ultimately prove useful for deciphering mechanisms of disease that are more relevant to OLD that occurs in the context of HCT.

Treatment of chronic lung injury after HCT

The accepted association between BO/OLD and chronic GVHD has led to a consensus that this form of late pulmonary toxicity is immunologically mediated. Therefore, once the diagnosis of non-infectious OLD is established, standard therapy has included a combination of enhanced immune suppression with supportive care (including bronchodilator and supplemental oxygen therapy) and broad-spectrum antimicrobial prophylaxis. Since airflow obstruction tends to be “fixed” rather than reversible, response to bronchodilator therapy is usually marginal. Similarly, responses to immune suppressive therapy (including various combinations of steroids, calcineurin inhibitors, and azathioprine) are limited, and are typically associated with preservation of remaining lung function rather than in significant improvement. Furthermore, no combination of agents has been shown to be particularly effective [93]. Given the inherent increased risks of opportunistic infection, the duration of immune suppressive therapy should be carefully considered if a clinical response is not seen within the first several months of treatment or when pulmonary dysfunction is longstanding. Patients with more severe disease at the start of treatment have a poorer prognosis and higher mortality rates, reinforcing the importance of early diagnosis. The poor response to standard therapy and the unacceptable morbidity and mortality experienced by afflicted patients has resulted in the consideration of lung transplantation in some HCT recipients with severe OLD [103] and underscore the need for a better understanding of the pathogenesis of disease [104].

Corticosteroids - systemic and inhaled

In 2009, a Consensus Conference on the diagnosis and treatment of chronic GVHD of the lung was held in Regensburg, Germany, resulting in a summary of accepted treatment options [91]. The conference recommended a combination of systemic and inhaled corticosteroids as front-line therapy for patients with BO/OLD. Although systemic corticosteroids form the backbone of therapy for both acute and chronic GVHD, there have been no randomized clinical trials to assess its efficacy in patients with BO/OLD. A small retrospective study noted stabilization of lung function in seven of nine patients treated with pulsed corticosteroids at 10 mg/kg/day [105]. No other prospective trials on systemic corticosteroids alone have been published. The potential additive benefits of inhaled steroids have been examined in a number of clinical trials, with variable results [106,107].

Azithromycin and FAM therapy

Several small case series have attempted to exploit the anti-inflammatory effects of the antibiotic azithromycin to treat BO/OLD in both allogeneic HCT and lung allograft recipients. Each study suggested a beneficial effect of this drug on pulmonary function when administered for 12 weeks or longer [108,109]. Treatment with fluticasone, azithromycin, and montelukast (FAM therapy) has been used at a number of medical centers and is now widely employed for BO/OLD management. A retrospective review of patients treated with FAM therapy noted a reduction in the use of systemic corticosteroids compared with matched historical controls treated with high-dose corticosteroids [110]. Prospective phase II and III clinical trials are currently in progress to examine the role of combination therapy with FAM in the management of BO/OLD [111].

Inhibition of TNF-α and other approaches

The potential role for TNF-α in the pathogenesis of both OLD and RLD suggests that agents such as etanercept, which neutralize this protein, may have promise, and studies have demonstrated a potential benefit of this drug in some HCT patients with chronic lung injury [97,112]. A phase II clinical trial using etanercept for the treatment of chronic lung injury after HCT was recently published [97]. Etanercept was administered for 4 or 12 weeks to 31 patients with either BO/OLD (n = 22) or RLD (n = 9). BAL procedures were performed pre- and post-therapy in all patients. The addition of etanercept therapy to conventional immune suppression was well tolerated, with no observable infusional toxicities and a limited frequency of opportunistic infections. Objective responses in pulmonary function were observed in one-third of patients with non-infectious OLD or RLD and the 5-year overall survival was 90% (95% confidence interval 73–100%) for those patients who responded to therapy. Study subjects showed increases in plasma levels of sTNFRI, sTNFRII, IL-8 and TGF-β at the time of study entry and attempts to identify biomarkers of OLD represent an ongoing line of investigation. The role of extracorporeal photopheresis (ECP) for management of BO/OLD has yet to be defined. A recent report of 10 patients undergoing ECP for BO/OLD noted stabilization in six of nine patients treated with extended courses of ECP therapy [113]. Finally, the administration of inhaled cyclosporine showed promise for lung allograft recipients [114], but studies in HCT recipients have not been reported.

Optimizing the management of patients with chronic pulmonary dysfunction

The comprehensive approach to patients with late lung toxicity includes completion of a thorough history and physical examination, assessment of pulmonary function and radiographic findings, consideration of bronchoscopy/BAL and procurement of lung tissue, and consultation with a variety of medical specialists (Figure 95.6). However, practice guidelines regarding (1) the frequency of medical surveillance (including completion of PFTs) to identify early onset of disease, (2) the optimal diagnostic approach (including the role of radiographic imaging, BAL/tissue procurement) once pulmonary dysfunction is identified, (3) clinical criteria for when to start and stop systemic or inhaled therapy, (4) the route, dose, class, and duration of immune suppressive and supportive care agents, and (5) consideration of lung allograft procedures in severely affected individuals have not been established. The outstanding diagnostic and therapeutic dilemmas that exist with respect to the management of BO/OLD were thoughtfully reviewed by Chien and Martin [93].

Although some centers recommend quarterly PFTs following day 100 post-HCT for routine screening, the frequency of and methods for such measurements vary widely across institutions. Once new pulmonary toxicity is suspected, chest CT scans are frequently considered. While air trapping on expiratory views supports a diagnosis of OLD, a normal radiographic appearance of the lungs is not uncommon, nor does it rule out the presence of developing lung disease. Using an overlay of inspiratory and expiratory views from routine high-resolution CT scans of the chest, investigators at the University of Michigan have adapted the parametric response map, a voxel-wise image analysis technique to assess the evolution and extent of lung disease in non-HCT patients with chronic obstructive lung disease. This novel attenuation mapping technique can detect evidence for small airway and parenchymal disease before changes are observed on conventional radiographic or PFTs [115]. Studies are ongoing to test and validate this approach in HCT recipients with and without suspected pulmonary dysfunction. The role of bronchoscopy and BAL in managing patients with OLD or RLD

Figure 95.6 Approach to HCT patients with late-onset respiratory dysfunction. The comprehensive approach to patients with late lung toxicity includes completion of a thorough history and physical examination, assessment of pulmonary function, and radiographic assessment. Results of the initial work-up will guide subsequent decision-making towards initiation of empiric antimicrobial therapy versus consultation with medical and surgical specialists and consideration of bronchoscopy/BAL and procurement of lung tissue. When pulmonary dysfunction is determined to be non-infectious in origin and immune suppressive therapy is considered, enrollment on open clinical trials is desirable whenever possible. BAL, bronchoalveolar lavage; CXR, chest X-ray; OLD, obstructive lung disease; PFTs, pulmonary function tests; RLD, restrictive lung disease; Tx, therapy.

also deserves further consideration. One of the more intriguing findings of the recent TNF-α inhibition trial was the preponderance of patients with suspected BO/OLD and RLD who had subclinical but active pulmonary infections [97]. All 57 patients enrolled in this prospective study underwent a pretherapy BAL and 20 (35%) were ruled ineligible for subsequent study therapy because pathogenic organisms were identified in the BAL fluid. Of note, none of the 20 patients exhibited clinical signs of acute or chronic infection. Hence, the high incidence of occult infections in this setting supports the consideration for bronchoscopy as part of the standard approach to this patient population.

Finally, what composite of correlative clinical data should trigger the initiation of systemic or inhaled therapy? Are FEV_1 values and FEV1/FVC ratios the best measures of OLD or are measurements of FEV_1/SVC or FEV_{25-75} more sensitive indicators of small airway obstruction? Should therapy be initiated based upon a specific percentage decline in FEV1 or FEV_1/FVC ratio over a specified time period, regardless of the absolute FEV_1 or FEV_1/FVC ratio? Thus, would patients with a >10–15% decline in FEV_1 over a defined period, but whose FEV_1 remains >75% of predicted, benefit from early interventional therapy? What therapies should be considered for patients with significant non-infectious RLD? Is this a manifestation of an alloimmune attack on the recipient lungs? If one considers the proposed triphasic model for the progression of chronic fibrotic pulmonary dysfunction (Figure 95.5), treating affected patients at the onset of bronchiolar (or interstitial) inflammation and prior to significant collagen deposition would have merit. Such an approach underscores the potential benefits of early detection and the procurement of lung tissue via trans-bronchial or surgical approaches.

Conclusion

Lung injury remains a significant problem following allogeneic HCT in both the immediate post-transplant period and in the months to years that follow. Although lung injury occasionally occurs following autologous HCT, the allogeneic response significantly exacerbates toxicity in both the acute and chronic settings. Historically, much of this injury was assumed to be due to occult and often unidentifiable infections, but a large preponderance of experimental data now demonstrates that non-infectious disorders such as IPS and BO have major immunologic components. Despite these findings, establishing the lung as a true target of GVHD remains a hotly debated topic. Like the gut and skin, the lung is a critical immunologic interface between the sterile body sanctuary and the outside environment. As such, the lung is a rich source of histocompatibility antigens and professional antigen-presenting cells and the site of complex immunologic networks. Inflammatory mediators such as TNF-α along with donor-derived effector cells, which contribute to GVHD, are associated with lung injury in the experimental and clinical settings. However, the absence of consistent evidence for epithelial apoptosis remains a major obstacle to considering the lung a target organ of acute GVHD. In the chronic setting, the lung is widely accepted as a target of GVHD. The clear similarities between the histopathologic features of OLD observed after allogeneic HCT and during lung allograft rejection strongly support this concept. The case for immunologic mechanisms contributing to RLD is evolving, but conventional wisdom has yet to embrace this form of lung dysfunction as a manifestation of chronic GVHD. However, in the absence of infection, it remains unclear what (if any) other process could be responsible for the influx of (donor) immune cells into the lung parenchyma and interstitial space. It is hoped that as animal models yield further insights, our understanding of these disease processes will improve and ultimately lead to new therapeutic strategies to diagnose, treat, and prevent pulmonary toxicity in our patients.

CHAPTER 96

Kidney and Bladder Complications of Hematopoietic Cell Transplantation

Sangeeta Hingorani
University of Washington, Seattle Children's Hospital, Seattle, WA, USA

Introduction

Renal dysfunction is a common complication of hematopoietic cell transplantation (HCT) and a major cause of morbidity and mortality. There are many definitions used to describe both the acute kidney injury (AKI) and chronic kidney disease (CKD) that occur after HCT (Table 96.1). The heterogeneous nature of the definitions, types of HCT, and diverse patient populations often make it difficult to draw comparisons across studies. The bladder is also commonly involved after HCT, and processes that affect the bladder can also lead to renal injury.

This chapter focuses on the epidemiology, pathogenesis, and treatment of renal and urologic problems. The time course of renal injury varies from days after transplant to months later. The difference between acute and chronic is arbitrarily defined by timing, as CKD usually refers to manifestations of renal disease that occur after day 100, and "acute" covers the early injury up to day 100. Similarly, bladder injury, most commonly hemorrhagic cystitis (HC), is divided into early onset and late onset, and the distinction between the two is also one of timing, lending itself to different etiologic factors. In this chapter, the early-onset or acute injuries will be discussed first, followed by the later or chronic injuries. The disease processes can overlap: AKI that persists is later termed CKD. Although this chapter discusses the injury that occurs after HCT, baseline or pre-transplant renal function can impact outcome [1]. Therefore, baseline assessments not only of serum creatinine, but also urinalyses and more formal estimations of glomerular filtration rate (GFR), are warranted. In addition, the hematopoietic cell transplantation-specific comorbidity index (HCT-CI) score (intermediate and high risk) is associated with an increased risk of AKI after HCT [2]. Accurate assessment of baseline renal function can help guide later medication dosing.

Acute kidney injury

Epidemiology

In the majority of studies of AKI in the HCT population, AKI is defined as a doubling of baseline serum creatinine within the first 60–100 days after HCT. The incidence of AKI varies from a low of 6.5% in autologous transplants to as high as 79% in patients admitted to the intensive care unit (ICU) after transplant. The incidence also varies based on the type of HCT and the conditioning regimen. AKI is more common in allogeneic transplant recipients than autologous transplant recipients, and high-dose regimens compared with reduced-intensity conditioning (RIC). The less severe, or grade 2, AKI is defined as less than a doubling of baseline serum creatinine with a >25% decrease in GFR. Grade 2 is a doubling of baseline serum creatinine without the need for dialysis, and grade 3 is dialysis-requiring AKF. Two new definitions proposed by nephrologists for AKI are based on the so-called RIFLE (risk, injury, failure, loss, and end-stage) criteria and the AKIN (acute kidney injury network) definition (Table 96.1). The stages are based on changes in GFR and serum creatinine and/or decreases in urine output. Risk is an increase in serum creatinine of 1.5× baseline or a decrease in GFR of >25%. Injury is a doubling of baseline serum creatinine or a 50% decrease in GFR. Failure is either a tripling of baseline serum creatinine, a serum creatinine of >4 mg/dL or a 75% decrease in GFR. Loss and end-stage refer to duration of renal failure of 1 and 3 months, respectively [3]. These criteria were established because the degree of renal failure affects outcome in adult patients admitted to the ICU. They are also applicable to the HCT population and should be used in future studies of AKI after HCT. Regardless of the definition chosen, increasing severity of AKI is associated with a stepwise increase in the hazard ratio of mortality [4–6].

Risk factors for AKI by type of conditioning regimen and transplant

High-dose conditioning regimens and allogeneic HCT

The incidence of AKI in these patients is as high as 69%. AKI in this group of patients occurs early after transplant, often before day 28. Risk factors for AKI in this group of patients include lung toxicity, hepatic toxicity, sinusoidal obstruction syndrome (SOS), amphotericin use, and sepsis [7–14] (Table 96.2). In a smaller study in Turkey, cyclosporine (CSP) use was associated with an increased risk of AKI after high-dose regimens, whereas sepsis played a major role in autologous recipients. It was also found that a low serum albumin at baseline increased the risk of later renal dysfunction [15]. Those patients who develop AKI after high-dose conditioning require dialysis more frequently and have a higher mortality than patients without AKI. In the patients who require dialysis, the mortality approaches 83%. In a meta-analysis of patients with AKI after HCT, AKI was an independent predictor of mortality [16].

RIC regimens and allogeneic HCT

In a retrospective cohort study comparing 140 high-dose versus 129 RIC transplant recipients, it was found that despite the older age of

the RIC patients and the greater percentage of patients with a GFR of <89 mL/min/1.73 m^2 at baseline, only 47% of patients developed AKI compared with 73% in the high-dose treatment group within the first 3 months post-transplant. AKI occurred slightly later in the RIC group, at a median of 26–60 days post-transplant. Fewer patients required dialysis in the RIC group (3% versus 12%) and mortality was significantly lower. The need for artificial ventilation increased the risk of AKI 10-fold in the RIC group of patients. Other risk factors included graft-versus-host disease (GVHD) and the source of the donor cells, with AKI being more common in patients who received marrow compared with peripheral blood, diabetes, SOS, sepsis, methotrexate use, and cytomegalovirus (CMV) reactivation [6,13,17–21].

Table 96.1 Definition of terms: A comparison of post-SCT AKI[a] definition and classification according to serum Cr levels in the RIFLE, AKIN, and grading criteria

RIFLE	
Risk	Increase in serum Cr ≥1.5 × baseline or decrease in GFR ≥25%
Injury	Increase in serum Cr ≥2.0 × baseline or decrease in GFR ≥50%
Failure	Increase in serum Cr ≥3.0 × baseline or decrease in GFR ≥75% or an absolute serum Cr ≥4.0mg/dL (354 μmol/L) with an acute rise of at least 0.5 mg/dL (44 μmol/L)
Loss	Persistent AKI >4 weeks
ESKD	ESKD >3 months
AKIN	
Stage 1	Increase in serum Cr ≥0.3 mg/dL (26.5 μmol/L) or increase to 150–199% (1.5–1.9-fold) from baseline
Stage 2	Increase in serum Cr to 200–299% (>2.0–2.9 fold) from baseline
Stage 3	Increase in serum Cr to ≥300% (≥3-fold) from baseline or serum Cr ≥4.0 mg/dL (354 μmol/L) with an acute rise of at least 0.5 mg/dL (44 μmol/L).
Grading	
Grade 0	Decrease in GFR <25% of baseline
Grade 1	Increase in serum Cr <2-fold from baseline with a decrease in GFR >25% but <50% of baseline
Grade 2	Increase in serum Cr ≥2-fold from baseline but not requiring dialysis
Grade 3	Increase in serum Cr ≥2-fold from baseline and need for dialysis

GFR, glomerular filtration rate; RIFLE, risk, injury, failure, loss of kidney function, and end-stage kidney disease; AKIN, acute kidney injury network; Cr, creatinine; AKI, acute kidney injury; ESKD, end-stage kidney disease.

[a] Post-SCT AKI is defined within the first 100 days after SCT.

High-dose conditioning regimen and autologous HCT

There are two case series of AKI in autologous transplant recipients. Compared with the allogeneic setting, the incidence is lower – approximately 21% – in patients after autologous HCT. In a study of patients with amyloid light-chain (AL) amyloidosis, risk factors for AKI identified at baseline included decreased creatinine clearance, proteinuria, and cardiac involvement. In addition, transplant-related risk factors included melphalan use and bacteremia. A second study of 232 women who underwent HCT for breast cancer found a similar incidence of AKI but identified liver and lung toxicity in addition to sepsis as risk factors for acute injury, similar to risk factors for AKI after high-dose conditioning followed by allogeneic transplantation. It has been suggested that the lower incidence after autologous HCT is related to the avoidance of calcineurin inhibitors (CNIs).

Pathogenesis of AKI after HCT

Although many risk factors have been associated with the development of AKI after HCT, only the most common ones are discussed in detail below (Table 96.3). Thrombotic microangiopathies (TMAs), including thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS), can occur early after HCT, but changes in serum creatinine may not be present at the time of diagnosis. TMAs are discussed in the section on CKD. Tumor lysis syndrome is a rare cause of AKI in patients after HCT, seen more commonly in patients with residual disease or an underlying lymphoproliferative disorder at the time of HCT. The renal injury is related to tubular obstruction and dysfunction secondary to hyperuricemia, hyperphosphatemia, and deposition of uric acid and phosphate within the kidney. Management involves the use of uric acid inhibitors, aggressive hydration, and, when needed, dialysis. Tumor lysis syndrome is relatively uncommon in the HCT population as most patients are in remission at the time of transplant.

Sepsis

Sepsis leads to a combination of insults, both hemodynamic and inflammatory, that coalesce to cause renal failure. The pathophysiology of AKI in this setting is complex and not well understood. There is an initial inflammatory response leading to cytokine-induced

Table 96.2 Summary of the literature on acute kidney failure (AKF) after hematopoietic cell transplantation (HCT)

No. of patients	Type of transplant	Incidence: autologous/ allogeneic (%)	Definition of AKF	Postulated risk factors	Onset time (days) (median)	Ref.
143	100% allogeneic	48.9	Grade 1 and 2	Increased bilirubin levels, SOS, aGVHD 3–4	33	[5]
232	100% autologous	21	Grades 2 and 3	Liver and lung toxicity, sepsis	28	[10]
170 pediatric	55.3% allogeneic myeloablative, 44.7% allogeneic non-myeloablative	45.7/17.1	Grade 2	Myeloablative conditioning	30	[178]
57	26% autologous, 73% allogeneic	60/79	Grades 2 and 3	Liver failure, low serum albumin, APACHE II score	27	[12]
269	100% allogeneic	60	Grades 2 and 3	Myeloablative conditioning, female gender, high-risk malignancy, comorbidity	22	[13]
147	100% allogeneic	36	Grade 2	SOS, amphotericin use	33	[14]
88	100% allogeneic	69	Grades 2 and 3	SOS, sepsis, lung and liver toxicity	16	[9]
47	53% autologous, 47% allogeneic	32/68	Grades 2 and 3	SOS, sepsis, cyclosporine	44	[15]
253	100% allogeneic, non-myeloablative	40	Grades 2 and 3	Ventilator use, GVHD, product source (marrow versus peripheral blood)	60	[19]
62	100% allogeneic, non-myeloablative	29	Grades 1–3	HLA match, 1 or >aGVHD, SOS, sepsis	38	[21]
96	37.5% RIC, 62.5% myeloablative	29.2	Grades 1–3	aGVHD	33	[7]

GVHD, graft-versus-host disease; SOS, sinusoidal obstruction syndrome.

Table 96.3 Potential risk factors and mechanisms for AKI in the HCT population

Intravascular volume depletion

systemic arteriolar vasodilatation and endothelial injury [22]. The resultant capillary leak that occurs leads to renal hypoperfusion. In addition, early after sepsis there is a constriction of the renal vessels, further decreasing renal perfusion. Injury to the tubules themselves causes a local release of cytokines and chemokines that cause local inflammation and further intrarenal injury [23]. In addition to the effects of sepsis, the medications used to treat the infections are often nephrotoxic. Several reports have identified amphotericin, in the conventional or liposomal formulation, as a risk factor for AKI.

Hepatic SOS

There is a well-known association between sinusoidal liver injury and renal insufficiency. It has been postulated that portal hypertension resulting from hepatic sinusoidal injury leads to both decreased renal perfusion and tubular injury, the former probably being the more important in the genesis of AKI. Clinically, SOS is associated with marked sodium avidity, low urinary sodium resulting in volume overload, edema, and weight gain, as seen in hepatorenal syndromes [24]. Weight gain likely serves as a marker of impending renal failure rather than being a result of the renal injury; in addition, the association between weight gain and the development of AKI described in the literature is conflicting [14,25]. Although some have advocated keeping weight gain per se to a minimum (<10% fluid overload) to improve outcome in this patient population, it is unclear whether the weight gain is causal or the result of other insults to these patients. Hence prevention of SOS may be the more important strategy.

Nephrotoxic medications

Although there are many potential nephrotoxic medications that are given to patients after HCT, the one that is most commonly associated with development of AKI is amphotericin. The finding by many of an increased risk of AKI among patients receiving amphotericin is not surprising because the nephrotoxicity of conventional amphotericin is well known, as is its association with renal failure in the HCT population [26–28]. However, in a study by Hingorani *et al.* [14], liposomal preparations of amphotericin were also associated with an increased risk of AKI. In the same study, neither the administration of vancomycin nor gentamicin in the 2 weeks prior to development of AKI increased the risk of AKI. In cord blood transplant recipients, vancomycin was associated with an increased risk of AKI post-transplant [29].

Use of amphotericin for fever of unclear etiology carries significantly increased risks of AKI in the transplant population. Given the marked increase in risk of AKI in patients who have received either conventional or liposomal amphotericin, we recommend that patients be treated with amphotericin only if clear indications exist, such as documented fungal infection or prolonged use of prophylactic triazoles. Fortunately, newer antifungal drugs such as fluconazole, itraconazole, voriconazole, and caspofungin are now available for indications formerly covered by amphotericin. Depending on the end-points chosen, each of these medications has been shown to be equally efficacious to amphotericin but with better safety profiles [30].

Management of AKI

In the majority of cases, the management of AKI is supportive. The choice of dialysis modality often depends on hemodynamic stability of the patient, degree of volume overload, and blood pressure, which makes it difficult to interpret outcomes as sicker patients are more likely to be placed on continuous renal replacement therapy. In two studies of pediatric HCT patients, those patients placed on convective therapies [continuous veno-venous hemofiltration (CVVH) or continuous veno-venous hemodiafiltration (CVVHDF)] rather than diffusive therapy had a better survival rate, especially when initiation of therapy was early, and in one study at the time of intubation and mechanical ventilation regardless of renal function and urine output [31,32]. What is apparent is that early intervention, regardless of modality choice, can improve outcome.

Chronic kidney disease

Epidemiology

The cumulative incidence of CKD varies from 13–60% in adult studies [33–35] to as high as 62% in children [36]. CKD usually becomes apparent 6–12 months after HCT, although it has been described as early as 2 months and as late as 10 years post-transplant. As in AKI, numerous definitions are used to define CKD in these patients. Most definitions are based on serum creatinine or an estimated or calculated measurement of GFR based on the Modification in Diet and Renal Disease or the Schwartz formula in children. The National Kidney Foundation has divided GFR into stages 1–5 based on an estimated GFR (eGFR) to help guide clinical treatment plans. The range of GFR is from ≥90 mL/min/1.73 m^2 with some renal damage for stage 1 to <15 mL/min/1.73 m^2 for stage 5 and end-stage renal disease (Table 96.4).

Many terms have also been suggested to describe the chronic forms of renal dysfunction occurring after HCT, including "bone marrow transplantation nephropathy" [33], "radiation nephritis" [37], and "conditioning-associated HUS" [38]. None of these terms defines the degree of renal dysfunction, anemia, or hypertension. The renal pathologies of bone marrow transplantation nephropathy, conditioning-associated HUS, and radiation nephritis are indistinguishable and may reflect a common injury. Total body irradiation

Table 96.4 National Kidney Foundation Kidney Disease Outcomes Quality Initiative: chronic kidney disease by stage

Stage	Description	eGFR (mL/min/1.73 m^2)
1	Kidney damage with normal or GFR	≥90
2	Kidney damage with mild ↓ GFR	60–89
3	Moderate ↓ GFR	30–59
4	Severe ↓ GFR	15–29
5	Kidney failure	<15 or dialysis

eGFR, estimated glomerular filtration rate.

(TBI) may play a role in the endothelial injury that leads to the development of a TMA and its subsequent renal injury.

In addition to a TMA, there are other manifestations of CKD in this patient population, including nephrotic syndrome and GVHD-related CKD. The latter form of CKD after HCT is often defined as abnormalities in serum creatinine or estimated and calculated GFR at 6–12 months after transplant. The lack of a consistent definition of post-HCT CKD has made it difficult to draw comparisons across studies, to identify risk factors for its development, and to devise prevention and treatment strategies.

Clinical syndromes of CKD after HCT

Acute kidney injury

AKI has been shown to be a risk factor for CKD in various adult and pediatric studies [14,35], suggesting that some patients do not recover fully from their AKI and progress to CKD.

TMAs: TTP and HUS

Definitions and clinical diagnosis

TMA syndromes represent a spectrum of clinical diseases characterized by systemic or intrarenal platelet aggregation, thrombocytopenia, and microvascular fragmentation of erythrocytes. Platelet aggregation can result in ischemia and organ injury. When renal injury is predominant, a diagnosis of HUS is usually rendered, while the presence of extensive extrarenal manifestations leads to a diagnosis of thrombotic TTP (reviewed in [39]).

TMA syndromes are not uncommon in the setting of HCT. In a series of both retrospective and prospective studies, the incidence of microangiopathic disease after HCT ranged between 2 and 21% [40–42]. The incidence seems to be lower in patients receiving high-dose conditioning regimens than in patients receiving RIC regimens [43,44]. TTP tends to occur early after transplant, whereas HUS seems to occur much later after transplant. When the presentation is fulminant, TMA syndromes are often associated with severe AKF and death. More commonly, however, they follow an indolent course, resulting in the eventual development of CKD.

For the diagnosis of TMA after HCT, the following clinical characteristics must be met: microangiopathic hemolytic anemia demonstrated by red blood cell fragmentation with two or more schistocytes per high-power field, elevated lactate dehydrogenase levels, renal dysfunction (defined as a >50% increase in baseline serum creatinine or a 50% decrease in creatinine clearance from baseline), and/or neurologic involvement without other identifiable causes, and a negative direct and indirect Coombs test [45]. The new grading system proposed is based on the common toxicity criteria for HCT TMA, and severity is based primarily on serum creatinine level, need for dialysis, and/or encephalopathy [45]. However, a comparison between the Clinical Trials Network definition of TMA and the International Working Group suggested that requirement of concurrent renal and neurologic dysfunction in the Clinical Trials Network definition and the requirement of ≥4% schistotocytes of the International Working Group definition could lead to exclusion of patients with probable TMA who are at high risk for a poor outcome [46]. Those patients with more severe forms of TMA have a higher risk of mortality [47].

Risk factors for TMA after HCT

Although no clear relationships have been found to date for the development of TMA after HCT, a number of risk factors have been examined. In earlier studies, where HUS was the primary diagnosis, risk factors identified were TBI [33,36,48] and CNI use [33,38,47,49,50]. However, in later studies of TMA, acute GVHD grades II–IV, older age, and transplant from an unrelated donor were the primary risk factors identified [40,42]. Other investigators have also identified SOS, grafts from matched unrelated donors or haploidentical donors, and lymphoid malignancy as significant predictors of TMA after HCT in addition to the above risk factors [11,51–53]. No decrease in the incidence of TMA has been found in patients undergoing RIC regimens, and it is thought that fludarabine may directly contribute to the endothelial injury in these patients [44,53]. In many of these cases, the renal injury is not present at the time of diagnosis of the TMA but occurs later in the course of the disease. TMA can also occur in the HCT population as a result of viral infections [54].

Total body irradiation

The entity known as “radiation nephritis” was described as early as the 1920s. The clinical course is variable and manifests as nephritis, hypertension, and proteinuria and/or anemia [55]. The time frame for each of these clinical presentations is also variable, with acute nephritis presenting 6–12 months after irradiation, and the subacute, chronic, and late forms occurring 2–5 years later. Although radiation can damage the vascular endothelium, tubular epithelium, and glomerulus, the primary site of injury has not been identified [55]. The doses of TBI traditionally associated with radiation nephritis are usually >2000 cGy [56]. To test the theory that radiation causes endothelial injury, Rubin and Casarett performed renal scans at several time points after irradiating rats unilaterally with 1000–6000 R [55,57]. A baseline renal scan outlined both kidneys and remained essentially unchanged for 3 months post-exposure. Between 3 and 6 months, subtle changes were noted, and at 9 months, the irradiated left kidney showed clearly diminished uptake of radiolabel. The changes on renal scan correlated with microangiopathic pathology showing poor vascularization and disruption of glomerular capillaries.

Given the variable time to presentation and degree of renal injury, a secondary insult(s) to the kidney may potentiate the radiation injury. For example, it is known that irradiated vessels are more sensitive to the effects of hypertension. It is therefore possible that hypertension in these patients may cause further vascular injury or impair the kidney’s ability to repair such injury. As with other dividing cells, radiation inhibits endothelial cell proliferation in culture [58]. The normal turnover time of endothelial cells is approximately 2 months [59], which may explain the delayed development of renal injury in some patients after HCT.

Based on the dose of radiation received, Miralbell *et al.* determined the risk of having an abnormal creatinine level at 18 months after HCT [60]. There appeared to be a dose-dependent relationship between radiation and renal injury. At a dose of 12 Gy, the relative risk was 2.9, and at a dose of 13.5 Gy, the relative risk was 8.4 compared with the group of patients who received 10 Gy. In a prospective study using renal shielding, a trend towards a decreased incidence of CKD was observed in the shielded versus the unshielded groups [48]. In this study, all patients received TBI in addition to cytarabine and cyclophosphamide as part of their conditioning regimen. Twenty of the 157 adults (13%) surviving beyond 100 days developed renal insufficiency; 18% were from the unshielded group and 10% were from the single-shielded group. No patients who received double shielding (diminishing the total radiation dose to the kidneys to 9.8 Gy) developed renal insufficiency throughout the follow-up period of 2.5 years. A retrospective analysis of 100 patients who underwent T-cell-depleted transplantations found that 11/70 patients who received TBI as part of their conditioning regimen developed TMA, whereas none of the patients who did not receive TBI developed a TMA. None of the patients received a CNI [61].

Immunosuppressive agents

Immunosuppressive agents have also been associated with the development of CKD. Agents such as CSP and tacrolimus can initiate HUS-like syndromes after HCT [33,41,47,49,50,53]. On histologic examination of kidneys from three HCT patients on CSP who died with renal failure, thrombus formation was observed in capillary tufts and arterioles with subendothelial and mesangial widening and sclerosis. Conversely, none of 55 patients not on CSP had renal capillary or arteriolar thromboses [62]. CSP is also a potent vasoconstrictor of the afferent arteriole of the glomerulus. In a small study of seven renal transplant recipients on CSP, decreases in GFR and renal plasma flow were found and correlated with CSP dose. The decreases seen here were transient and reversed as drug levels returned to normal [63]. The nephrotoxic effects of CSP correlate with serum levels of the drug and duration of therapy. CSP is also known to cause arteriolar injury, glomerular sclerosis, and interstitial fibrosis, in addition to diffuse expansion of the mesangial matrix [64]. Studies of pediatric cardiac transplant patients also found an association between CSP use within the first 2 months after transplant and decreases in GFR years after transplant [65]. High CSP levels (>500 μg/L) in the first 6 months after cardiac transplant were associated with the development of end-stage renal disease at any time after cardiac transplant [66]. However, in a study of approximately 69,000 patients receiving a non-renal transplant including heart, lung, liver, intestine, and combined heart–lung, CSP use at initial hospitalization was associated with only a slightly increased risk of developing CKD after transplant [hazard ratio (HR) = 1.24, 95% confidence interval (CI) 1.17–1.30] [67]. In both adult and pediatric studies, the combination of sirolimus and a CNI, whether used for prophylaxis of GVHD or treatment, has been associated with an increased risk of TMA compared with CNIs alone [68–70]. The numbers in these studies were small; however, 11–23% of patients developed TMA and it seemed to be associated with high levels of tacrolimus, sirolimus, or both. This risk may be higher in heavily pretreated patients, such as those undergoing their second HCT [70]. Close monitoring of levels and clinical and laboratory signs of TMA are warranted in patients on combination therapy. In some cases, discontinuation of sirolimus, tacrolimus, or both was needed to improve signs and symptoms of TMA.

Histopathology of TMA after HCT

Microscopic examination of kidney biopsy specimens from patients with TMA-associated CKD demonstrates mesangiolysis and loss of endothelial cells with expansion of the subendothelium and occlusion of capillary loops (Figure 96.1). On electron micrographs, there is extensive widening of the space between the glomerular basement membrane and the subendothelium with amorphous deposits that are not immune complexes. Recent renal pathology studies of renal biopsy specimens and autopsy specimens have demonstrated staining of C4d, a complement split product, in glomerular and peritubular capillaries, suggesting an antibody-mediated process and complement activation as the cause of the endothelial injury in the cases of TMA. Patients also had evidence of tubulitis and peritubular capillaritis in their kidneys. The median time to biopsy or autopsy was 7 months post-transplant and all patients had either acute or chronic GVHD. Five of the seven patients did not have clinical evidence of TMA at the time of biopsy or death but did have elevations in serum creatinine and proteinuria/hematuria [71].

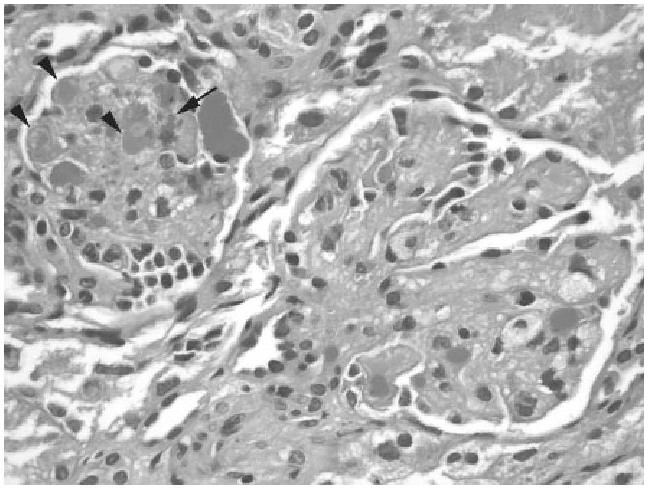

Figure 96.1 Thrombotic microangiopathy. The glomerular mesangium is fibrillary and blends with unapparent capillary lumina that are obscured by markedly swollen endothelial cells that impart a "bloodless" appearance. Fibrin thrombi fill some of the capillaries in the left glomerulus (arrowheads), which has erythrocyte fragments in the mesangium (arrow). (Hematoxylin and eosin; magnification: ×200).

Pathophysiology of TMA after HCT

Regardless of the offending agent, endothelial damage is thought to represent the inciting factor in the development of TMA syndromes (Figure 96.2). Endothelial injury activates the coagulation system, leading to thrombin formation and fibrin deposition. The ability to repair such injury depends on the balance between fibrinolytic and coagulant activity [72]. Although histologically similar, TMA appears to be distinct from TTP, in that TA-TMA patients do not have markedly low levels of ADAMTS13 [73,74]. Current theories on the pathogenesis of renal endothelial injury include hypotheses based on abnormalities of the coagulation cascade and the complement system [75,76].

More recent studies have identified both acute GVHD grade II–IV and chronic GVHD as risk factors for the development of TMA. Endothelial injury has been described in patients with chronic GVHD, and it is thought that endothelial cells are direct targets of cytotoxic donor T-lymphocytes in these patients [77]. The risk of TMA injury in the kidney may be secondary to circulating inflammatory cytokines related to GVHD elsewhere in the body or may reflect direct injury to endothelial cells of the kidney by GVHD. Plasma markers of endothelial injury and coagulation activation are elevated in patients with acute GVHD after HCT, suggesting an association between endothelial injury, acute GVHD, and the subsequent development of TMA [78,79]. Loss of function of vascular endothelial growth factor (VEGF) or inhibition of VEGF leads to the development of proteinuria and glomerular endothelial injury consistent with TA-TMA [78], and lower levels of VEGF have been associated with more severe forms of acute GVHD [79]. Perhaps GVHD leads to endothelial injury in the kidney through a reduction in serum VEGF levels and therefore loss of the protective effects of VEGF on the glomerular filtration barrier. The increased risk of TA-TMA in recipient–donor gender mismatch pairs further supports the theory that acute GVHD may play a role in the pathogenesis of TA-TMA after HCT [80].

An association between inflammatory cytokines, interleukin-6, interleukin-8, and tumor necrosis factor-alpha (TNF-α) and the

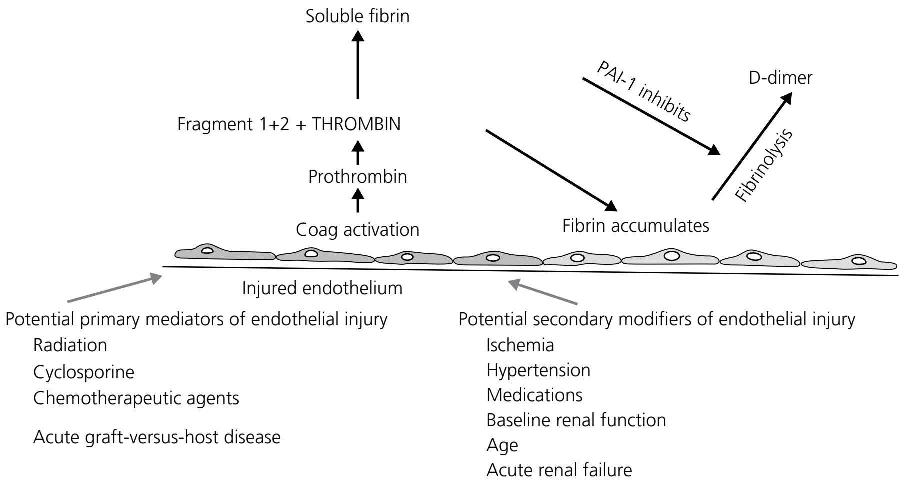

Figure 96.2 Potential risk factors and pathophysiology of thrombotic microangiopathy after hematopoietic cell transplantation. PAI-1, plasminogen activator-1.

balance between ultralarge von Willebrand factor release from endothelial cells and the rate of breakdown by ADAMTS13 resulting in thrombosis has been described [81]. Other investigators have found systemic release of TNF-α correlated with levels of PAI-1 and tissue plasminogen activator release, supporting the idea of cytokine-induced endothelial damage [82].

Natural history of TMA after HCT

Several studies have been carried out to elucidate the clinical course of TMA-related CKD following HCT. Again, most have involved small numbers of patients and have had a relatively short follow-up (1–5 years) [33,36,83–85]. What is apparent from the studies reported is that often an acute deterioration of renal function is followed by a period of stabilization, but rarely is full renal function restored. Patients with CKD after HCT can progress to end-stage renal disease and have decreased survival compared with other patients with end-stage renal disease [86].

In the study by Cohen *et al.* of 149 patients who survived 100 days or more after HCT during 1985–1990, 19 (13%) developed HUS within 6–12 months after transplantation [33]. Four patients progressed rapidly to end-stage renal disease with a clinical picture resembling HUS; three of the four died. The one surviving patient had a markedly diminished GFR of 17 mL/min (normal 80–100 mL/min). Seven patients suffered a more gradual but continual decline, and the remaining eight patients had stabilization of their renal function after an initial period of decline. Four of the seven patients eventually progressed to dialysis. Elevated lactate dehydrogenase levels and lower platelet levels seemed to predict a poor prognosis.

Nephrotic syndrome

Chronic GVHD may manifest itself in the kidney as nephrotic syndrome with or without renal insufficiency (reviewed in [87]). Patients usually present with proteinuria, edema, and hypoalbuminemia. The majority of these case reports demonstrated membranous nephropathy with subepithelial deposits on biopsy; it is postulated that these deposits are antigen–antibody complexes representing GVHD in the kidney (Figure 96.3).

However, cases of minimal-change disease (MCD), which is thought to be a T-cell-mediated process, have been described [87] and one case in a cord blood transplant patient without GVHD was thought to be associated with recipient T-cell activation leading to both graft failure and MCD [88]. Comparisons between case reports of membranous nephropathy and MCD after HCT have found that membranous nephropathy occurs in 61% of cases compared with 22% of cases with MCD [89]. The majority of reported patients with membranous nephropathy were male, slightly older, and had a history of acute and chronic GVHD. Both MCD and membranous nephropathy occur later after transplant at 8 and 14 months, respectively, and tend to occur within 1–5 months of the development of GVHD and/or the tapering of immunosuppression for chronic GVHD. Membranous nephropathy is more difficult to treat, with only 27% of patients reported achieving remission compared with 90% of patients with MCD. Others have reported cases of diffuse proliferative glomerulonephritis, antinuclear cytoplasmic antibody-related glomerulonephritis, focal segmental glomerulosclerosis, and immunoglobulin A nephropathy [90–94] occurring after HCT. The development of each of these diseases seems to be associated with chronic GVHD and/or tapering of immunosuppression. Treatment with high-dose prednisone and/or reinstitution of CNIs usually results in resolution of nephrotic syndrome. Some physicians have used rituximab successfully in patients with nephrotic syndrome after HCT, typically in cases of membranous nephropathy [95].

GVHD-related CKD

Many survivors with CKD after HCT will not present with nephrotic syndrome, meet the definition of a TMA, or have a documented viral infection, and therefore are labeled idiopathic CKD. The incidence of idiopathic CKD varies from 13% in patients receiving high-dose conditioning to 16–66% in patients who have been treated with RIC. Risk factors identified in the high-dose group include older age, TBI, CSP use, AKI, and acute and chronic GVHD. In the RIC transplant group, long-term CNI use and prior autologous transplant, and also AKI and GVHD, were associated with an increased risk of CKD.

However, in other studies, TBI was not associated with an increased risk of CKD [96]. Miralbell *et al.* found that those patients receiving a lower dose of TBI because of renal shielding actually had greater decreases in GFR at 4 months compared with patients who received higher doses of TBI. The effects were no longer apparent

after 12 months following HCT [97]. In a cohort study of 142 children undergoing HCT over a period of 5 years in The Netherlands, Kist-van Holthe *et al.* [98] found no correlation between radiation dose used and renal insufficiency at 1 year. In a large, retrospective study of 1635 HCT patients, TBI, irrespective of dose (range 200–1600 cGy), was not associated with the development of CKD after adjusting for demographic data and baseline characteristics, including original diagnosis, donor type, transplant type, and transplant year [34]. In the same study, TBI (HR = 1.0, 95% CI 0.7–1.4) was not associated with an increased risk of CKD among patients who received an allogeneic graft (n = 1228).

The finding that GVHD is a risk factor for the development of CKD in patients after HCT who may not present with nephrotic syndrome or evidence of TMA [34,35,97] suggests that either the kidney is a direct target organ of GVHD via T-cell-mediated renal damage or the chronic systemic inflammatory state of GVHD leads to CKD (Figure 96.4). A third explanation is that chronic exposure to CNIs, such as CSP, leads to CKD. These are not mutually exclusive hypotheses as T-cell-mediated injury in GVHD is intertwined with cytokine effects [99]and the effects of CSP may be potentiated

in the presence of a chronic inflammatory state. In an autopsy study of renal pathology in six autologous and 20 allogeneic HCT patients, renal tubulitis identical with that seen in renal allograft rejection was present in 67% of patients, whereas a later study found that only 12% of patients had tubulitis associated with more severe forms of GVHD [100,101]. In a case report of minimal-change nephrotic syndrome after HCT, large numbers of $CD8^+$ donor T cells were found infiltrating the interstitium and periglomerular areas of the kidney [102]. In a mouse model of GVHD in which the kidneys were examined, venulitis, endothelialitis, and tubulitis were present as early as 2 weeks post-transplant. This lymphocytic inflammatory process then progressed, and by 6 months more severe endothelialitis and venulitis were present along with an increased number of peritubular infiltrates [103]. The authors suggested that these findings represent a continuous process of tissue injury that is different from the early injury that is seen in other target organs of GVHD [103]. This observation may explain why CKD often occurs beyond the first 3 months after transplant.

The inflammatory and cytokine cascade that accompanies GVHD may also affect the kidney without invoking the T-cell-mediated injury that is present in GVHD involving the skin, gut, and liver [104,105]. In support of this hypothesis, several studies have demonstrated that elevations in plasma cytokine levels correlated with the development of post-transplant complications and organ dysfunction in the HCT population [106,107]. In animal models of GVHD, tissue destruction of acute GVHD does not require alloantigen expression on the target epithelium for cellular cytotoxicity but can be mediated by inflammatory cytokines [108]. In a case report of minimal-change nephrotic syndrome post-HCT, increased production by donor T cells of TNF-α and interferon-gamma was related to the development of nephrotic syndrome; the lack of cellular infiltrates on biopsy suggested that the glomerular injury was secondary to cytokine production stimulated by alloantigens at extrarenal sites [107].

In addition to the T-cell activation and cytokine release in acute GVHD, chronic GVHD also involves the activation of B cells and the production of cytokines, including transforming growth factor-beta (TGF-β_1) [109]. TGF-β_1 is important for collagen synthesis and matrix deposition in the kidney and other organs [110,111] and may also be important in the development of CSP-associated nephropathy in non-renal transplant patients [112]. The effects of CSP on the kidney can be potentiated by increases in the production of TGF-β [113]. All CKD is not secondary to TBI or CSP use but rather a combination of factors including GVHD and the chronic inflammatory state that accompanies it.

Albuminuria and CKD

Albuminuria, defined as a urine albumin-to-urine creatinine ratio (ACR) of 30–299 mg/g creatinine, is thought to be a marker of endothelial dysfunction and inflammation, reflecting a systemic endothelial injury that affects multiple organs including the kidney. Newer work postulates that albuminuria results from tubular dysfunction in the trafficking and degradation of albumin [114,115]. In a prospective study of 142 patients with normal baseline serum creatinine undergoing their first HCT, ACRs were measured as an early marker of renal injury. Urine samples were collected weekly from baseline to day 100 after transplant. Total (intact) monomeric albumin was determined in untreated urine samples by liquid chromatography. Albuminuria was defined as an ACR (mg/g creatinine) over 30 and overt proteinuria as an ACR of 300 or more.

The prevalence of albuminuria at baseline, day 100, and 1 year was 37, 64, and 50%, respectively. Overt proteinuria occurred in 4% of patients at baseline, 15% at day 100, and 4% at 1 year. Characteristics associated with albuminuria include age, gender, donor type, hypertension, and acute liver injury with portal hypertension, but not exposure to TBI. Early albuminuria increased the risk of acute GVHD and sepsis, but not AKI. Albuminuria at day 100 was associated with CKD at 1 year (odds ratio = 4.0, 95% CI 1.1–14.6). Non-relapse mortality risk was elevated (HR = 6.8, 95% CI 1.5–50.6) among patients with overt proteinuria at day 100, and overall survival was decreased [116]. Other studies have suggested that proteinuria may be an early marker of TMA [117]. In studies with longer follow-up, the prevalence of proteinuria was 22.8% in patients at a median of 6 years post-HCT [4].

Given the increased risk of mortality in patients with proteinuria at day 100 post-HCT, a renal biopsy may benefit these patients as we can better understand the pathophysiology of proteinuria and the role of GVHD and chronic inflammation in the development and progression of CKD in these patients. Perhaps proteinuria is a marker of GVHD and/or its effects in the kidney and in those patients with evidence of inflammation on biopsy, continuation of immunosuppression at day 100 may be warranted even in the absence of GVHD elsewhere in the body. There is evidence in patients with diabetes and albuminuria that treatment with an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin receptor blocker (ARB) slows the progression of CKD [118,119]. Extrapolating from the studies in the diabetic population, we speculate that ACEIs and ARBs would be useful in patients with albuminuria after HCT.

Hypertension and CKD

In pediatric and adult HCT recipients, Majhail et al. reported a hypertension prevalence of 70% during the first 2 years with a median time to onset of 1 month post-transplant [120]. Almost 90% of these patients were receiving drug therapy. Cyclosporine use was an independent risk factor for hypertension. Other studies have reported a hypertension prevalence of 15–72%, depending on the length of follow-up [8,35,121–123]. In a retrospective analysis of children and adults followed for a median of 16 years, the prevalence of hypertension was 17% [124]. Antihypertensive therapy was prescribed for 65% of patients with hypertension. Independent predictors of hypertension include AKI, TBI, autologous transplant (mostly neuroblastoma), obesity, and diabetes. Hypertension has been associated with a fourfold increased risk of CKD [4].and with the development of TA-TMA [8,61,117].

Effective treatment of hypertension is important for decreasing cardiovascular risk and slow the progression of CKD [8,125]. Blood pressure screening should be performed at all follow-up visits, and at least once per year [120,123,126]. ACEI or ARB therapy should be considered first-line chronic therapy, given their antiproteinuria and renoprotective properties [127,128]. However, caution must be exercised in those with hyperkalemia, AKI, and females of reproductive age. Additional therapeutic options should include sodium restriction and lifestyle medication [124].

Treatment of TMA and GVHD-related CKD

Although the described pathology of the kidney in selected patients with CKD after HCT has demonstrated microangiopathic changes or changes associated with nephrotic syndrome, the pathophysiology of idiopathic chronic renal injury after HCT remains obscure. Histopathology is often not obtainable because patients with CKD after HCT are often not considered candidates for biopsy because of the perceived risks of the procedure in this patient population.

Therapeutic options for the treatment of TMA after HCT are limited. Case series of plasma exchange have been described, with mixed results [53,129,130]. One study suggests that plasma exchange may be beneficial in patients with TMA in the absence of active acute GVHD only [131]. Potential offending agents such as CSP and tacrolimus have been discontinued with some improvement clinically, but again the response depends on the severity of disease. Also, in some cases, where acute GVHD is contributing to disease, resolution of TMA has not occurred until GVHD was treated [53]. Given the finding of GVHD as a risk factor for the development of TMA, some authors have hypothesized that an immune etiology may be a contributing factor and attempted to treat TMA with rituximab. In a case report, four of five patients who developed TMA after HCT were successfully treated with rituximab [132]. In a report of 12 patients with TTP early after transplant, 50% of them responded to treatment with defibrotide [133]. In a series of 13 patients with TMA, substitution of daclizumab, an anti-CD25 antibody, for the CNI and sirolimus for treatment of GVHD resulted in complete remission in five and partial remission in two patients; however, only four of the 13 patients survived [134].

Based on treatments used in animal models, primarily of radiation-induced HUS, there are other potential interventions for patients with HUS after HCT. ACEIs have been used in rodent models of HCT-related renal injury, with intriguing results. The use of captopril or enalapril at the time of TBI in these animals resulted in less azotemia, lower blood pressures, and long-term preservation of renal function [56]. In addition, when it did occur, the onset of renal dysfunction was delayed and there was a decrease in proteinuria. However, these mouse models were of radiation-induced injury, and since it is likely that TBI does not play a role in GVHD-related CKD, it may be that the potential beneficial effects of ACEIs and ARBs in these patients are their potential to reduce blood pressure and also inflammation and inflammatory markers in patients. A randomized controlled trial of captopril in 50 patients demonstrated a trend towards a decrease in the development of CKD at 1 year post-HCT and an improvement in patient survival. Given the small numbers of patients, the differences did not achieve statistical significance [135]. There have been case series of patients undergoing renal transplantation successfully after HCT, and it is a viable option for patients with end-stage renal disease after HCT [136–138]. In patients who received their kidney from the same donor as their hematopoietic cells, little or no immunosuppression is required.

Bladder complications after HCT

Hemorrhagic cystitis

Epidemiology

Hemorrhagic cystitis (HC) is a common complication after HCT and a significant cause of morbidity. Clinical syndromes vary from microscopic hematuria to macroscopic hematuria, dysuria, and flank pain with or without renal insufficiency. The grading system for HC based on the National Cancer Institute Common Toxicity Criteria defines grade 1 as the presence of microscopic hematuria, grade 2 as the presence of gross hematuria without clots managed with hydration and diuresis, grade 3 as persistent gross hematuria or clots that require cauterization or transfusions, and grade 4 as gross hematuria that requires surgical intervention. In some studies, HC has been divided into early onset (within 48 hours of the conditioning regimen) and late onset (occurring any time after 48 hours). Early onset is often attributed to the toxic effects of conditioning regimen, including the use of cyclophosphamide, whereas late onset is thought to be related primarily to viral infections [139,140].

Early-onset HC

Early-onset HC occurs during conditioning therapy with cyclophosphamide with or without TBI. Acrolein, a breakdown product of cyclophosphamide, is directly toxic to the bladder mucosa and is one of the primary causes of early-onset HC. The risk of HC from cyclophosphamide is dose dependent [141]. In a retrospective analysis of 81 patients who developed HC at one institution, Tsuboi *et al.* found that sodium 2-mercaptoethanesulfonate (mesna), often used as prophylaxis against HC, increased the risk of developing early-onset HC fivefold, and bladder irrigation increased the risk ninefold; additionally, the use of busulfan in the conditioning regimen was associated with an increased risk of early-onset HC [140]. The authors hypothesized that the combination of mesna and busulfan had a synergistic effect; however, mesna alone also led to increased risk of early-onset HC. The authors suggested that mesna itself may be toxic to the bladder mucosa. These findings contradict others in the literature (described in the section on treatment) regarding the use of mesna.

Late-onset HC

Both BK polyoma virus and adenovirus are known to cause HC after HCT; however, it is not clear whether viremia and viruria leads to renal insufficiency or HC in all patients [142,143]. Pre-transplant anti-BK virus immunoglobulin G titers of 1:20 or more increased the risk of BK viruria in patients, but donor BK viral serology was not associated with a risk of reactivation of BK infection in patients who were seronegative at the time of transplant [144]. In addition, peak BK viral load (≥3 log increase from baseline) in the urine has been shown to increase the risk of HC in patients after HCT [144]. In a study of 130 HCT patients, 51% had antibodies to adenovirus prior to transplant. In this study, risk factors for clinical adenovirus infection were positive antibody status of the donor and grade IV acute GVHD [145]. In a report of 21 patients, adenovirus was implicated in the development of acute renal failure (ARF) after HCT in 90% of the patients [146]. Additional case reports of ARF associated with adenovirus have been described [147]. Other risk factors that have been identified for late-onset HC include older age, pre-transplant conditioning with busulfan, allogeneic HCT, and acute GVHD grade II–IV [140,144,148,149]. Risk factors in children include male gender and unrelated donor graft recipients [150].

Treatment of HC post-HCT

First-line management of HC often involves supportive care, increased hydration and diuresis, and occasionally continuous bladder irrigation. In a randomized prospective study by Bedi *et al.*, no difference was found between the use of mesna versus forced diuresis during the conditioning regimen to prevent the development of early-onset HC secondary to the uroepithelial toxicity of conditioning [151]. One hundred patients were randomized to receive mesna or hyperhydration to prevent HC during conditioning therapy. Patients in the mesna arm received 1.5 mL/m^2/day of fluids compared with the 3 mL/m^2/day of fluids given to the patients in the hyperhydration arm. Again, no difference was found in the incidence of early-onset HC [152]. Ballen *et al.* found that hyperhydration with 5% dextrose normal saline with potassium at 250 mL/hour was more cost-effective and a well-tolerated alternative to the

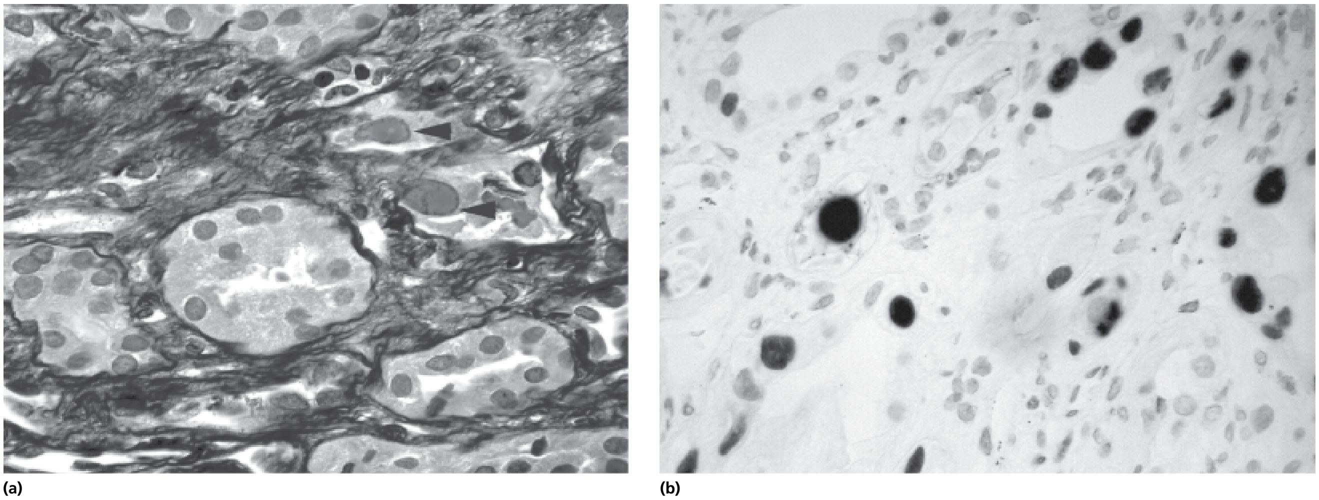

Figure 96.5 BK nephropathy. (a) The nuclei of tubular epithelial cells infected with BK virus have basophilic inclusions and peripheral chromatin rimming (arrowheads). (Methenamine–silver–hematoxylin; magnification: ×400). (b) Infected nuclei stain positively with antibodies directed against the large T antigen of SV40. (Diaminobenzidine; magnification: ×400).

use of mesna to prevent early-onset HC attributed to cyclophosphamide used for conditioning. The nursing time involved to monitor these patients carefully and avoid volume overload was not factored into the cost [153].

A third randomized study evaluated hyperhydration with continuous bladder irrigation or continuous mesna infusion. The incidence of early-onset HC was similar in the two groups but, as expected, the continuous bladder irrigation group had more hematuria. There was a significantly higher number of urinary tract infections in the bladder irrigation group, and these patients reported more discomfort, restriction of movement, and bladder spasms than the mesna group [154]. Based on these studies, it is clear that hyperhydration and maintenance of adequate diuresis are important. Most centers use mesna when cyclophosphamide-based conditioning is used, but it may not offer additional benefit if hydration and diuresis are adequate. Continuous bladder irrigation should not be used to prevent HC unless patients have markedly decreased or no urine output. It may have a role in dissolution of clots in more severe forms of HC.

There are numerous case reports of improvements in symptoms and stabilization of renal function in patients with HC secondary to BK or adenovirus HC treated with cidofovir [155–160]. Ciprofloxacin has also been shown to reduce BK viral replication, decrease the risk of BK reactivation, and quantitatively decrease BK viruria [161], and the authors suggested that it may be beneficial to prevent BK-associated HC [162]. Leflunomide has been used to treat both BK nephropathy in renal transplant patients and CMV infections in HCT patients with promising results and may have a role in the treatment of BK nephropathy in the HCT population (reviewed in [163]). There are isolated case reports of the successful use of intravesicular sodium hyaluronate [164], prostaglandin E2 [165], and cidofovir [157] to treat virally induced HC in patients after HCT. Previous intravesicular therapies have been tried (including formalin, alum, and silver nitrate), with varying results and many complications secondary to therapy (reviewed in [166]). Intravenous ribavarin for adenovirus-associated HC and factor VIIa have also been used successfully to treat HC in patients after HCT [167,168]. Other therapies that have been reported to manage the bleeding associated with severe HC include selective embolization of vesical arteries [169] and cystectomy in a patient who developed renal failure and pulmonary edema secondary to ongoing HC after HCT [170]. There is one case report of the use of hyperbaric oxygen therapy to treat intractable HC successfully [171]. In cases of HC where obstruction of urine flow occurs, percutaneous nephrostomy tubes or ureteral stent placements may be necessary to relieve the obstruction and allow drainage of the urine.

There have been case reports of patients with biopsy-proven BK nephropathy (Figure 96.5) after transplant resulting in CKD and in some cases end-stage renal disease requiring dialysis [172]. Thus, in patients with BK viruria after transplant, it is important to measure serum BK levels by the polymerase chain reaction as these have been associated with the development of CKD and renal failure [172]. Serum BK levels are more reflective of renal involvement and, in renal transplant patients, are associated with BK nephropathy in the graft. After HCT, a blood BK level of >10,000 copies/mL has been associated with the development of HC [173]. Similarly, Haines et al. reported that children with a peak plasma BK viral load of >10,000 copies/mL during the first year after HCT, regardless of urine viral load, had worse renal and urological disease compared with those with viremia of <10,000 copies/mL [174]. BK viremia was an independent predictor of the development of renal injury in patients post-HCT [175]. In cases of BK viremia or nephropathy, first-line therapy is often reduction of immunosuppression when possible prior to institution of cidofovir and other antiviral agents. A renal biopsy should be performed in patients with BK viremia and elevated serum creatinine levels prior to initiation of cidofovir to confirm the diagnosis of BK nephropathy. In the absence of biopsy-proven BK nephropathy, cidofovir may not be indicated.

Complications and imaging findings with HC

Various complications have been described in patients who develop HC after HCT; these include hydronephrosis, obstructive uropathy [141,150], ureteral obstruction secondary to clot formation and/or ureteral stenosis [176], necrotizing tubulointerstitial nephritis [147], and ARF [126,132,133,136,141,146,147,150]. Bladder perforation has also been described [150], as has intractable hemorrhage requiring cystectomy.

Imaging findings of HC will vary based on severity of disease and imaging modality. On renal and bladder ultrasonography, focal or diffuse bladder wall thickening can be seen [177]. Clots may be visible within the bladder, and if the clot is causing an obstruction, unilateral or bilateral hydronephrosis may also be visualized. Sloughed debris secondary to obstruction, clot, inflammation or infection can also cause obstruction and is visualized on ultrasound. In the presence of hydronephrosis, additional imaging studies such as a voiding cystourethrogram and a lasix renogram may be necessary to differentiate obstruction versus reflux. Additionally, the upper tracts may be involved, and thickening of the suburothelial lining of the renal pelvis has been described. Perinephric fluid collections secondary to hemorrhage or rupture of a fornix can also be found. With the addition of Doppler studies to the ultrasound, decreased flow to areas of the bladder and also hypervascularity and areas of active bleeding can be identified. Direct visualization with cystoscopy and cauterization of areas of active bleeding may be necessary. Computed tomography and magnetic resonance imaging can enhance the images and may offer more definition of the bladder wall than ultrasound. However, first-line imaging in cases of HC should be carried out with ultrasound and Doppler studies.

Conclusion

There are clearly distinct clinical entities involving the kidney that occur after HCT: ARF, TMA, nephrotic syndrome, and GVHD-related CKD. HC is the most common urologic complication reported in patients after HCT.

There are patients who will develop CKD that is not related to TBI or the conditioning regimen, but rather to complications and/or therapy that occur after HCT, specifically acute and chronic GVHD and prolonged CNI use. The burden of management will fall not only on the nephrologists, but also on the transplant physician to ensure close monitoring of renal function, blood pressure, and urinalyses post-transplant. It may be that our energies have been misdirected in trying to reduce exposure to TBI and that we should rather try to decrease the inflammatory and cytokine effects of GVHD and reduce exposure to CNIs to prevent CKD in this population of patients.

Although physicians are well attuned to HC after HCT, increasing awareness regarding the potential for both BK and adenovirus to lead to nephropathy, both acute and chronic, is needed. Careful monitoring of patients after the acute hemorrhage is controlled may be needed to prevent ongoing injury. Imaging with renal ultrasound is an important aspect of managing the acute complications such as obstruction but may also be helpful in monitoring ongoing injury and late complications.

Renal injury after HCT is a relatively common occurrence. As the indications for and number of transplants performed worldwide increase, so will the burden of kidney disease. Identifying those patients at risk for the development of both AKI and CKD will be important for potential intervention and prevention of kidney injury and progression to end-stage renal disease in this patient population.

CHAPTER 97

Endocrine Complications Following Hematopoietic Cell Transplantation

Fouad R. Kandeel and Behrouz Salehian
City of Hope National Medical Center, Duarte, CA, USA

Introduction

The advent of hematopoietic cell transplantation (HCT) has resulted in a significant extension of life for many children and adults affected with hematologic, immunologic, genetic, and metabolic diseases; however, the conditioning regimens for HCT, and also the process of HCT itself, may lead to some new complications for some patients. As continued improvements in post-HCT survival rates now often span decades, the manifestation of long-term endocrine complications in terms of growth, skeletal development, metabolic function, and gonadal and sexual function has become increasingly recognized, and the goal of maintaining an extended, superior quality of life post-HCT has likewise attained even greater importance. This chapter reviews the endocrine abnormalities that may result from HCT, and outlines suggested approaches to the investigation and management of these disorders.

Hypothalamic–pituitary dysfunction

Radiation exposure can result in hypothalamic–pituitary dysfunction in the following three clinical situations: (1) radiotherapy of brain or extracranial tumors (doses ≥30 Gy), (2) cranial radiotherapy for acute lymphoblastic leukemia (ALL) (doses 18–24 Gy), and (3) total body irradiation (TBI) prior to HCT for hematologic malignancy or solid tumors (doses 10–14 Gy). Since the functions of the hypothalamus and the pituitary are intimately related, it is not always easy to discriminate between damage at these two levels. In general, however, the hypothalamus is more radiosensitive than the pituitary, and more often the site of damage [1]. Hyperprolactinemia, for example, often occurs following external radiotherapy to the hypothalamic–pituitary area, suggesting a reduction in dopamine secretion by the hypothalamus. The degree of pituitary dysfunction is typically related to the dose of irradiation received; hypopituitarism has been observed with cumulative total doses of ≥20 Gy to the brain [2]. The threshold radiation dose may be lower in patients treated simultaneously with high doses of methotrexate or intrathecal chemotherapy; however, Kauppila et al. [2] noted that hypopituitarism was not seen after TBI doses of 12 Gy. In fact, it is generally thought that, in most cases, the hypothalamic–pituitary axis remains intact after HCT, and that hormonal disturbances usually occur as a result of injury at the target endocrine organ [2]. Nevertheless, it is possible that lower doses of cranial irradiation prior to HCT in patients with hematologic malignancies may cause hypopituitarism and/or long-term hypothalamic–pituitary hormone insufficiency. In contrast, end-organ hormone disturbances are common post-HCT, even with chemotherapy-only regimens [2]. Further discussions of the pathophysiology of specific hormone disorders, and methods for their investigation and treatment, are presented in the respective sections below.

Growth disorders

Pituitary growth hormone (GH) is secreted in a pulsatile manner that is superimposed on a schedule of diurnal variation. GH secretion is stimulated by growth hormone releasing-hormone (GHRH) and suppressed by hypothalamic somatostatin. GH stimulates the production of insulin-like growth factor (IGF)-1 proteins by the liver, which, in turn, exerts negative feedback control on the secretion of hypothalamic GHRH and pituitary GH itself (Figure 97.1). The immediate neonatal period generally represents the highest level of GH secretion. GH levels then decrease throughout childhood, but rise during puberty as a result of increased pulse amplitude (but not frequency). GH secretion falls once again with increasing age.

The anabolic effects of GH on the linear growth of bones are mainly mediated by IGFs and their binding proteins (IGFBPs), which extend the serum half-life of the IGFs by aiding in their transport to target cells and modulating their interactions with membrane surface receptors. Given that IGF-1 concentrations are more dependent on GH than IGF-2, the measurement of IGF-1 levels is more likely to provide useful clinical correlations in the evaluation of GH deficiency.

GH also has direct metabolic effects, such as lipolysis, increased amino acid transport into tissues, and increased liver protein synthesis. Further, GH is a diabetogenic hormone, and its excesses can produce insulin resistance via altered post-receptor insulin action, resulting in decreased carbohydrate utilization and impaired glucose uptake into cells. GH additionally increases hepatic glucose output, which further worsens hyperglycemia.

GH deficiency in the adult may be associated with reduced lean body mass and musculature, increased body fat, reduced bone mineral density (BMD), reduced exercise performance, and increased plasma cholesterol, comprising an overall increased mortality risk from cardiovascular disease. Further, adults with GH deficiency may suffer from depression, anxiety, reduced energy, and social isolation. Despite these observations, there are

Younger age at transplantation

no clinical syndromes of adult GH deficiency that have been widely recognized.

It is believed that the type of conditioning regimen prior to HCT has a significant influence in the development of potential growth dysfunction (Table 97.1). A large body of data suggests that radiation (particularly cranial and TBI) is mostly responsible for diminished growth in children who have undergone HCT. Potential pathogenic mechanisms include the direct impact of combination chemotherapy and radiation on the skeleton (i.e. skeletal dysplasia, particularly of the spine), radiation-induced hypothalamic–pituitary dysfunction, and hypothyroidism. Radiation may also prompt the development of precocious puberty, which can result in premature epiphyseal fusion and subsequent reduced final height. Children who have received preparation regimens consisting of cranial irradiation followed by high-dose chemotherapy and single-dose TBI are most likely to demonstrate growth defects 2–5 years after HCT, with pubertal growth most affected. With no previous cranial irradiation and fractionated TBI, however, growth was not compromised 3 years after HCT [1].

Because GH deficiency is strongly related to irradiation, growth rates may be adversely affected by HCT; in fact, GH deficiency is found in 32% of children after HCT with TBI [4]. Inadvertent exposure of the liver and other tissues during TBI via secondary radiation may additionally contribute to the defective production of essential growth factors such as IGF-1 [2]. Nevertheless, reports of final short stature after HCT range from 4% [5] to 60% [6], and other sources report final stature that generally falls within the normal adult range [1]. This variability in final height outcome may be attributable to the different patient ages at HCT, as the risk of impaired growth is highest in the youngest children transplanted prior to the onset of puberty; conversely, some reports have noted improved growth after HCT with younger patient age [7].

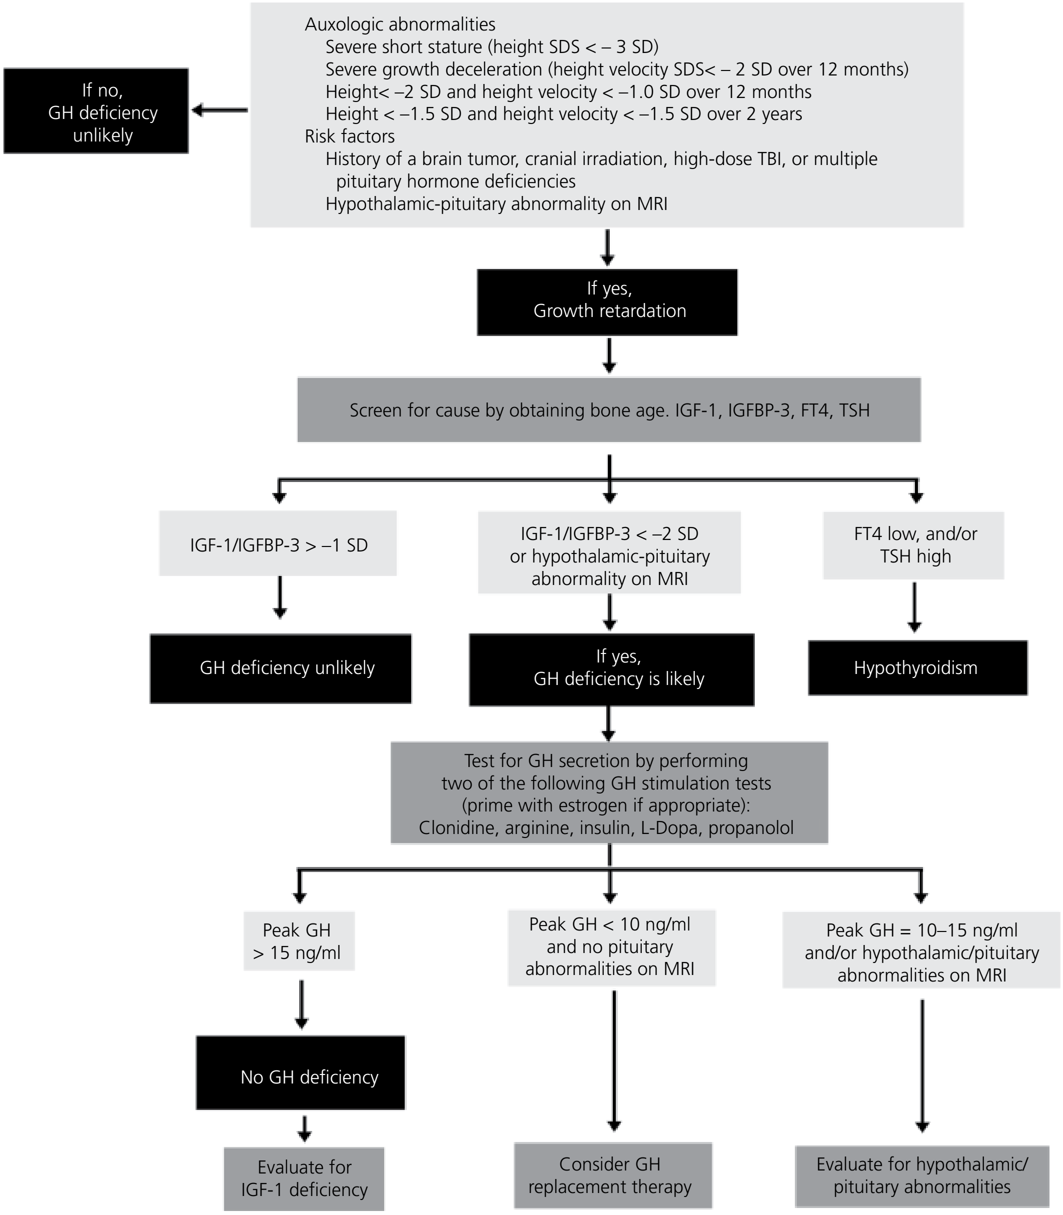
In the absence of cranial irradiation, there is actually a poor correlation between GH production and concentrations of IGF-1 or IGFBP-3 and growth in children after HCT, suggesting the influence of other factors on growth dysfunction in addition to primary GH deficiency. Endogenous or exogenous glucocorticoid excess, for example, may blunt GH secretion. Chemotherapy alone, particularly BU–CY (busulfan–cyclophosphamide), may cause growth deficiencies due to toxicities at the epiphyseal growth plate, even after corticosteroid administration has ceased. Additional considerations include nutritional or vitamin deficiencies, genetics, the nature of the underlying disease (e.g. red cell aplasia, Fanconi anemia, thalassemia), and the presence of general illness or graft-versus-host disease (GVHD). The manifestation of other endocrine hormonal dysfunction may further contribute to impaired growth dynamics. As another example, bone age advancement can be severely delayed in hypothyroidism – usually more so than with GH deficiency – and epiphyseal dysgenesis may be seen when calcification of the epiphyses progresses. The administration of gonadal sex steroids for the treatment of hypogonadism may cause premature growth cessation by accelerating the fusion of long bones and the closure of the growth plates, but the absence of these factors during the prepubertal period appears to have no major significance. As with sex steroids, glucocorticoid deficiency seems to have little effect if the individual is otherwise healthy (i.e. if hypotension and hypoglycemia are absent).

Evaluation of growth disorders post-HCT

Children should be closely monitored and serially measured for appropriate growth (height velocity) after HCT in the context of normal standards, such as the growth charts provided by the National Center for Health Statistics (NCHS), part of the Centers for Disease Control (CDC). Height velocity standards remarkably encompass the range of normal growth patterns between 2 years of age and puberty with great predictability, hence any deviation of the patient's plotted growth from the normal curve should be immediately suspect for an aberrant growth process. Growth potential may be estimated by the measurement of "bone age," or the level of ossification of the tubular bones, via radiographs of the left hand and wrist. Final adult height may be predicted with greater accuracy with increasing bone age.

In the assessment of growth hormone levels, the possibility for hypothalamic or pituitary dysfunction must always be considered, particularly with known radiation exposure and the presence of other endocrine hormone abnormalities [thyroid-stimulating hormone (TSH), adrenocorticotropoid hormone (ACTH), gonadotropin, etc.) and potential worsening of the underlying disease process (e.g. local extension of Hodgkin disease of the nasopharynx to the hypothalamus).

The identification of actual GH deficiency, however, is not often easily established, owing to low levels of basal GH secretion in both normal and truly GH-deficient patients. Further, the sequential



Auxologic abnormalities
Severe short stature (height SDS < – 3 SD)
Severe growth deceleration (height velocity SDS< – 2 SD over 12 months)
Height< –2 SD and height velocity < –1.0 SD over 12 months
Height < –1.5 SD and height velocity < –1.5 SD over 2 years
Risk factors
History of a brain tumor, cranial irradiation, high-dose TBI, or multiple pituitary hormone deficiencies
Hypothalamic-pituitary abnormality on MRI
If no, GH deficiency unlikely
If yes, Growth retardation
Screen for cause by obtaining bone age. IGF-1, IGFBP-3, FT4, TSH
IGF-1/IGFBP-3 > –1 SD
IGF-1/IGFBP-3 < –2 SD or hypothalamic-pituitary abnormality on MRI
FT4 low, and/or TSH high
GH deficiency unlikely
If yes, GH deficiency is likely
Hypothyroidism
Test for GH secretion by performing two of the following GH stimulation tests (prime with estrogen if appropriate): Clonidine, arginine, insulin, L-Dopa, propanolol
Peak GH > 15 ng/ml
Peak GH < 10 ng/ml and no pituitary abnormalities on MRI
Peak GH = 10–15 ng/ml and/or hypothalamic/pituitary abnormalities on MRI
No GH deficiency
Evaluate for IGF-1 deficiency
Consider GH replacement therapy
Evaluate for hypothalamic/ pituitary abnormalities

Figure 97.2 Algorithm for the evaluation of growth dysfunction following HCT. FT4, free thyroxine; GH, growth hormone; IGF-1, insulin-like growth factor-1; IGFBP-3, insulin-like growth factor binding protein-3; SDS, standard deviation score; TSH, thyroid-stimulating hormone. Source: adapted from Reiter and Rosenfeld 2008 [8].

measurement of spontaneous GH secretion is cumbersome and expensive. The development and availability of sensitive radioimmunoassays for IGF-related proteins have greatly simplified the diagnostic process (Figure 97.2). Thus, the laboratory workup for GH deficiency should primarily involve the measurement of IGF-1 and IGFBP-3 levels, and also the results of stimulated GH secretion. GH secretion can be stimulated with either physiologic (fasting, sleep, exercise) or pharmacologic stimuli (levodopa, clonidine, glucagon, propranolol, arginine, insulin). GH deficiency may generally be suspected in cases of subnormal growth velocity combined with GH levels <10 ng/mL after each of two pharmacologic stimulations carried out on two separate occasions. Testing should be performed after an overnight fast in order to prevent carbohydrate or fat ingestion from suppressing a GH response. Nevertheless, pulsatile secretion of GH may cause varying results.

Management of growth disorders post-HCT

It has been suggested that GH should be administered to children with decreased clinical growth rates, and/or decreased IGF-1 and IGFBP-3 levels, and/or low GH values on stimulation tests, while giving due consideration to the potential necessity of replacing other deficient hormones necessary to achieve optimal growth. Although no randomized trial has yet been reported that clearly delineates the benefits of GH treatment in children, some available long-term outcome data are promising with regard to positive growth response to treatment. In a French study [9], GH therapy of children who received TBI and/or cranial irradiation for leukemia resulted in a median gain of height that was equal to 0.59 × Z score (standard deviation from their aged-match peers). The benefit was greater in girls than boys.

Supplementation is commonly given with a starting dose of recombinant human growth hormone (rhGH) 0.18–0.35 mg/kg body weight per week, administered in seven daily doses. GH treatment after HCT typically results in an increase in growth velocity, albeit smaller than in children with idiopathic GH deficiency. Age at the initiation of treatment is inversely correlated with expected growth responses, possibly indicating the need for early treatment. First-year height velocity is the most predictive factor with regard to later growth that may occur in years 2–4; GH therapy in children typically is given for 2 years, but can be extended until the closure of long bone epiphyses if there are no contraindications. Suboptimal response to GH therapy may be attributed to poor compliance, improper administration, subclinical (undiagnosed) hypothyroidism (see later discussion), underlying illness, concurrent glucocorticoid therapy, prior irradiation of the spine, epiphyseal fusion, the presence of anti-GH antibodies (which develop in 10–20% of patients receiving rhGH), or an incorrect diagnosis of GH deficiency. It has not yet been possible to determine the link, if any, between GH therapy and the new development of leukemia; if present, the risk of leukemia subsequent to GH therapy appears to be limited to children already at high risk for that disease (e.g. prior malignancies, radiation exposure, the presence of syndromes associated with leukemia), but further studies are needed. In the National Cooperative Growth Study of more than 19,000 children treated with rhGH, no evidence of increased risk of recurrence of leukemia or central nervous system (CNS) tumor was observed [10].

The treatment of prepubescent HCT recipients with GH deficiency in addition to hypogonadism can be challenging; generally, administration of exogenous sex steroids is low in dosage or is postponed altogether until the desired patient height is reached in order to reduce the likelihood of premature closure of the growth plates.

Dysfunctional bone metabolism and osteoporosis

Certain hematologic malignancies (lymphomas) may also be associated with hypercalcemia and high levels of 1,25-dihydroxyvitamin D_3 (leading to increased calcium absorption). Increased bone resorption and impaired renal excretion contribute to hypercalcemia.

The loss of bone mass, or compromised bone strength, has been well documented as a sequel to HCT, preferentially within the first 6 months post-transplant. The mechanism of bone loss is complex and related to the effects of HCT on bone marrow stem cells. Typically, a 5–15% loss of bone mineral density (BMD) can be expected in the lumbar spine and femoral neck within 1 year after HCT [11]. Osteopenia is observed in as many as 50–60% of all HCT recipients, and osteoporosis develops in 20% [12]. Studies in adult survivors of childhood cancer demonstrate that BMD is reduced at multiple skeletal sites, supporting the premise that inadequate bone mineralization during childhood may have long-term adverse effects on BMD in adulthood [13]. The only study to have reported BMD in children after HCT using dual-energy X-ray absorptiometry (DEXA) technology showed that BMD was significantly lower than in adults [14]. Fracture rates in both male and female pediatric HCT recipients have been estimated at 172 per 10,000 person-years by one center (J. E. Sanders, unpublished data, cited in [15]); when compared with the peak childhood fracture rate of 133 per 10,000 person-years in a large, population-based cohort study of boys and girls [16], this suggests that reduced BMD in children as the result of HCT may be clinically significant.

In transplanted adults, several studies have confirmed that bone loss due to osteopenia or osteoporosis may occur even prior to HCT, due in part to the direct effects of underlying hematologic cancers on the integrity of bone, such as malignant changes in bone structure, particularly with acute leukemia or multiple myeloma. In one study, 39% of patients demonstrated evidence of osteopenia or osteoporosis prior to HCT in the lumbar spine, and 25% in the femoral neck; these numbers increased to 50% and 45% by 1 year after transplant, respectively [11].

In general, the pathogenesis of metabolic bone dysfunction is multifactorial and not completely understood, particularly with regard to the effects of high-dose treatment followed by HCT on bone mineral metabolism. The three major pathogenic mechanisms thought to be responsible for reduced BMD are (1) failure to achieve peak bone mass (due to altered calcium or vitamin D homeostasis, or deficiencies in growth or gonadal hormone secretion), (2) bone loss caused by increased bone resorption (disturbance in osteoclast function), and (3) inadequate replacement of lost bone due to decreased bone formation (disturbance in osteoblast function). HCT and post-transplant therapies may specifically affect bone homeostasis by inducing premature menopause and/or hypogonadism, directly poisoning bone cells, and altering calcium and magnesium metabolism, causing elevated parathyroid hormone (PTH). The leading cause of reduced BMD after HCT is prolonged glucocorticoid therapy for GVHD, likely due to the production of cytokines that trigger inappropriate osteoclastic activation, decreased bone formation, and decreased levels of 1,25-dihydroxyvitamin D_3. Glucocorticoids affect trabecular bone more than cortical bone, resulting in fractures of the vertebrae, ribs, and the ends of long bones. Bone loss is most rapid within 6 months of initiating glucocorticoid therapy, and may occur with doses as low as prednisone 5 mg daily. The use of chemotherapy and, to a lesser extent, radiation therapy as part of the pre-transplantation regimen exacerbates bone loss, due to the dose-dependent toxicity of high-dose chemotherapy to bone marrow osteoprogenitors, TBI-related radiation damage, and the suppressive effects of both of these modalities on the gonads. Cyclosporine, for example, potentiates hypomagnesemia and hypocalcemia. Physical inactivity due to long hospitalization or illness and nutritional deficits further compound these effects. Additional general risk factors include older age, thin body habitus, family history of osteoporosis or low-trauma fractures, smoking, and a diet low in calcium or vitamin D.

Interestingly, at the end of the first year post-transplantation, bone mass either begins to recover (spine and total body), or bone loss is attenuated (femoral sites); however, one study has shown that femoral bone loss is not regained. Improvement in bone mass is likely due to multiple factors, including a reduction in immunosuppressant dosage, resolution of immobilization or malnutrition, and convalescence from the transplant procedure itself. Long-term bone loss is mainly determined by the intensity of steroid use and untreated hypogonadism.

Osteonecrosis, or avascular necrosis, is not infrequent, and indeed is a significant sequela of HCT, affecting 10% of allo-bone marrow transplant (BMT) recipients in a single-center study [17]. Avascular necrosis seems to be related to a decreased number of bone marrow CFU-f colonies in vitro and may be facilitated by regeneration of mesenchymal stem cells (MSCs) and low osteoblast numbers. The mean time between HCT and development of osteonecrosis is 15 months.

Osteonecrosis involves bone infarction and the rapid and focal deterioration of bone quality that primarily affects the femoral head, although the ankles and shoulders may also be involved. Osteonecrosis is painful, and may lead to the ultimate collapse of the bone, often necessitating a hip replacement. Osteonecrosis can occur in all age groups, but is usually related to the use of corticosteroids, as glucocorticoids inhibit osteoblast function; relatively low doses, or even brief courses of high-dose therapy, have been implicated. The cumulative incidence of osteonecrosis after HCT is 5–20% at 5–15 years post-BMT, as osteonecrosis often occurs long after transplantation [18]. It is difficult to separate the effects of chronic inflammation on the microvasculature versus glucocorticoids in the development of osteonecrosis. In one large retrospective study among 4388 patients, the reported odds ratio of osteonecrosis was 3.75 for acute GVHD and 3.52 for chronic GVHD. Severity of GVHD was also associated with osteonecrosis.

Other risk factors for osteonecrosis include the presence of sickle cell disease and other hemoglobinopathies, polycythemia vera and other lymphoproliferative disorders, pregnancy, septic emboli, alcoholism, pancreatitis, Gaucher disease, lupus, rheumatoid arthritis, trauma (fracture/dislocation or direct tissue damage), radiation (direct injury to vascular supply leading to occlusion), and Cushing disease. Osteonecrosis of the jaw is also a rare complication of bisphosphonate therapy.

Evaluation of metabolic bone dysfunction post-HCT

Bone loss and fractures may present with pain and loss of function, negatively impacting quality of life. The strongest risk factors for metabolic bone dysfunction post-HCT are female gender and older age. Among the other factors, corticosteroid use is most significant; however, the dose–effect curve for steroid use in the development of osteoporosis is still not completely clear, and prospective data are sparse, hindering the ability to establish general recommendations for the prophylaxis and treatment of bone mineral loss post-HCT. The significance of the changes in BMD after HCT with regard to fracture risk has not been established. Long-term fracture risk is not only determined by BMD; vertebral fracture itself is a potent risk for future fracture, and also a history of falls and attributes of bone geometry. In children, growth charts, radiographic assessment of bone age, serum levels of IGF-1 and IGFBP-3, and GH provocation tests may be used to monitor for the occurrence of growth dysfunction, and possible metabolic bone disease (see the previous section for further discussion). In patients with demonstrated osteoporosis, it is reasonable to check serum calcium, magnesium, and 1,25-dihydroxyvitamin D levels. In adults, dual-energy X-ray absorptiometry (DXA) is currently the best and most well-referenced method to diagnose transplant-related bone loss. DXA may be performed as part of the pre-transplantation evaluation in order to assess the degree of bone loss before transplantation. After transplantation, bone densitometry can be repeated yearly for the first 2 years; if decreased BMD is seen, then densitometry is continued annually; otherwise, densitometry can be repeated every 3–5 years. DXA is also the most common method for measuring BMD in children, now that age-related normative reference data are currently available [19]. Bone turnover can also be measured by markers such as urinary hydroxyproline, urinary *N*-telopeptide cross-linked collagen, and serum osteocalcin. Once osteonecrosis is established, almost any imaging modality will reveal its presence, although magnetic resonance imaging (MRI) has the best sensitivity and specificity.

Management of metabolic bone dysfunction post-HCT

The prevention and treatment of osteoporosis focus on therapeutic modalities that act either to decrease the rate of bone resorption or to increase bone formation. The aggressiveness of disease intervention depends upon the degree of osteoporosis and the severity of bone loss, including T-scores and a history of prior fractures. Management should be tailored to each patient's specific response to therapy, level of tolerance to adverse effects, and the complicating presence of other concurrent illnesses.

For adult patients with osteopenia, calcium, vitamin D supplementation, and weight-bearing exercise are recommended. Patients should be counseled with regard to lifestyle management (exercise, smoking cessation, limiting alcohol intake) and instructed on body mechanics and posture in order to minimize the risk of falls. Treatment of osteopenic adults with chronic GVHD or osteoporotic patients should additionally include oral or intravenous bisphosphonates. Denosumab is a monoclonal antibody acting against receptor-activated nuclear kappa B ligand (RANKL) that has been shown to be highly effective at reducing bone loss in patients with osteoporosis, and decreases the rate of vertebral, non-vertebral, and hip fractures of both sexes. Denosumab is also effective in hypogonadal men and women, including those on glucocorticoid therapy, making it an appropriate choice for menopausal female patients [20].

In a large prospective study, pamidronate 90 mg per month for a period of 12 months was started prior to conditioning, and was found to be superior to placebo in reducing bone loss compared with calcitriol and calcium; however, femoral neck bone density after 1 year of therapy was still 2.8% below the baseline BMD [21].

Patients with Hodgkin disease and a history of mantle radiation therapy, however, already have a high risk (35%) for the development of breast cancer [22]; in these cases, selective estrogen response modulators (SERMs) such as raloxifene may be utilized, although venous thrombosis is a risk. Osteonecrosis of the jaw (ONJ) is a serious but rare complication of amino bisphosphonate therapy in adults (and also denosumab); however, the incidence of ONJ may approach 1% when bisphosphonates are administered intravenously and monthly to adults for the management of bone malignancy, and may occur more frequently in this setting after recent dentoalveolar trauma [23]. Oral bisphosphonates have been implicated less frequently as a cause of ONJ among patients without malignant bone disease, but have the potentially severe side effect of esophagitis. Intranasal or injectable calcitonin may be employed to alleviate pain related to bone fractures, but it has not proved useful in preventing or treating osteoporosis itself. Intermittent administration of injectable, low-dose, synthetic (recombinant human) PTH or a peptide analog as anabolic therapy has been shown to produce substantial increases in trabecular bone mass with little loss of (and even gains in) cortical femoral bone, and has reduced the risk of fractures. PTH may be reserved for patients in whom antiresorptive therapy is insufficient at preventing fractures, and may be particularly useful in steroid-induced osteoporosis. Patients must be monitored for the occurrence of hypercalcemia and hypercalciuria, however. Recombinant PTH cannot be used in patients who have received radiation therapy to the skeleton owing to the potential risk of osteosarcoma.

BMD should be evaluated in children at 3 months after allogeneic HCT, with an initial follow-up DEXA scan at 1 year [15]. Supplementation with calcium, vitamin D, and weight-bearing exercise is recommended, although these measures have not proved effective in preventing osteopenia, osteoporosis, or fractures when administered individually. As noted above, sex hormone replacement therapy has increased bone mass in both adult women and men, and is recommended for hypogonadal adolescents if age-appropriate [24,25]. Bisphosphonate therapy may also be pursued in pediatric patients, as some evidence seems to suggest that it may improve mean annualized BMD in children and adolescents after HCT by 33%, which is threefold higher than in children receiving calcium and vitamin D alone [15]; however, the effects of various pretreatment regimens were not sufficiently randomized in this study, and the group receiving bisphosphonates also had a higher proportion of patients receiving GH therapy and sex hormone replacement. The long-term effects of bisphosphonate and denosumab treatment in children remain to be established. Denosumab has been used in children for the treatment of osteogenesis imperfecta with acceptable safety [26].

Vitamin D deficiency

It is estimated that 1 billion people around the world are deficient in vitamin D [27]. Vitamin D deficiency has been linked to various inflammatory diseases; however, the mechanism by which vitamin D reduces inflammation is unclear.

Vitamin D deficiency and GVHD

Vitamin D deficiency has been demonstrated in a large number of subjects with autoimmune disease, and in GVHD. It remains unclear, however, whether vitamin D deficiency is the cause or the consequence of disease. In patients undergoing allogeneic stem-cell transplantation (allo-SCT), it was reported that 70% of patients were vitamin D deficient on day 0 and 87% were deficient on day 100 [28]. The high incidence of vitamin D deficiency in allo-SCT patients emphasizes the need for further study of the impact of vitamin D deficiency on clinical outcomes.

Vitamin D receptor (VDR) is upregulated during alloreactivity [29], suggesting that vitamin D consumption and possibly deficiency may play a role in the development of GVHD. It has been hypothesized that vitamin D may reduce GVHD in the allo-SCT setting through its tolerogenic effect on maturation towards Treg cell production [30], and also a direct inhibitory effect on T cells [31].

The idea of vitamin D-targeted therapy was used by a group of investigator in Spain to modify the course of GVHD [32]. In their retrospective study, the outcome of chronic graft-versus-host disease (cGVHD) in a series of 12 patients receiving vitamin D because of osteopenia or osteoporosis (confirmed by bone densitometry) after allo-HCT was assessed. These patients also had active cGVHD at the time when vitamin D treatment was initiated. Interestingly, there was a marked improvement in cGVHD for most of these patients, without appreciable secondary effects observed. This study was observational and retrospective, however, and therefore had significant limitations related to the methodology used.

Factors that contribute to low vitamin D_3 levels among patients undergoing bone marrow transplantation are lack of exposure to sun, anorexia and poor intake, and malabsorption and diarrhea due to chemotherapy or development of GVHD. Another possible explanation is the rapid metabolization of vitamin D.

The dose necessary to treat hypovitaminosis D during bone marrow transplantation needs further study. Observational experience suggests at least 2000 units PO of cholecalciferol daily among those in whom the level of 25-hydroxyvitamin D is between 20 and 30 ng/mL, provided that the level of PTH is elevated. In the absence of elevated PTH, the therapy may not be necessary. If the level of vitamin D_3 is between 10 and 20 ng/mL, the recommended empirical therapy consists of 5000 units of cholecalciferol daily; if the level is less than 10 ng/mL, a dosage of 10,000 units daily is needed. Vitamin D should be taken with meal for better absorption. Since the half-life of cholecalciferol is long, its level needs to be monitored regularly.

Thyroid dysfunction

Overall, thyroid dysfunction is a common disorder. Similarly, thyroid dysfunction of any type is the most common endocrine complication after allogeneic and autologous bone marrow transplantation (HCT), occurring in up to about half of patients. There is existing controversy over which aspects of HCT are most responsible for thyroid dysfunction: the process of HCT itself, the conditioning regimens used prior to HCT, or patient-related parameters (Table 97.2, Figure 97.3).

Radiation therapy involving the head and neck can lead to the occurrence of thyroid dysfunction, via direct damaging effects to the

thyroid tissue (primary dysfunction), and to the hypothalamus or pituitary gland. Further, the use of pre-transplant cranial or neck irradiation (e.g. for Hodgkin disease) is also implicated in the significant increase in rates of thyroid dysfunction post-HCT, including frank hypothyroidism, decreased thyroid reserve, hyperthyroidism, thyroiditis, the occurrence of thyroid nodules, and thyroid malignancy. Similarly, the use of total body irradiation (TBI) or total lymphoid irradiation (TLI) during the preparation regimen of HCT is associated with a greatly increased risk of some type of thyroid dysfunction occurring in the months to years after transplantation. The incidence of thyroid dysfunction is also higher in patients given single-dose irradiation (23–73%), rather than fractionated (10–28%) doses [33,34].

In one study, the prevalence of hypothyroidism appeared to be higher among children receiving HCT for severe aplastic anemia (SAA) than for leukemia, although this difference appeared to be the result of the type of GVHD prophylaxis used, rather than the disease itself (Figure 97.4). Patients with SAA who received methotrexate alone appeared to be at increased risk for developing thyroid dysfunction, but the reasons for this are unclear. It is possible that additional immunosuppression with methotrexate, antithymocyte globulin (ATG), and prednisone suppressed immunologic injury of the thyroid gland, whereas methotrexate alone following TLI may be comparatively inadequate to prevent thyroid injury. On the other hand, patients with acute leukemia, having received greater immunosuppression from TBI and previous long-term chemotherapy, may not require additional immunosuppression to avoid this type of radiation-induced "immune" thyroid injury [35].

Overall, the most common thyroid-related complications post-HCT are either functional in type [hypothyroidism due to destruction of thyroid tissue or autoimmune thyroid disease (AITD)], or present as mass lesions of the thyroid (benign nodular goiter, or malignant carcinoma) (Table 97.3). The prevalence of thyroid abnormalities is higher in allogeneic than in autologous HCT recipients [37], even in the absence of TBI [37,38]. In fact, Tourbert et al. [38] noted a remarkably high incidence of both frank hypothyroidism (10–15%) and euthyroid sick syndrome (ETS) (48% at 3 months after treatment) in a patient group who had received only a BU- or CY-based conditioning regimen without TBI, or had a history of previous radiotherapy (Table 97.4). ETS is actually the most commonly observed endocrine dysfunction in the 3-month period after HCT, and is typically characterized by low free triiodothyronine (T3), free thyroxine (T4), or both, with normal, elevated, or low TSH, along with an increased serum level of reverse T3, without pre-existing hypothalamic–pituitary and thyroid gland dysfunction (Table 97.5). A short-term fall in thyroid hormone levels after HCT generally reflects ETS, with increased conversion of T4 to reverse T3 (metabolically inactive), rather than intrinsic

change in the hypothalamic–pituitary–thyroid (HPA) axis. Thus, patients with ETS-related thyroid function abnormalities are not considered to have hypothyroidism. Notably, however, the occurrence of significant post-HCT ETS, as defined by a precipitous drop in serum total T4 levels, is predictive of lower survival rates compared with patients who do not develop ETS (34.5% vs. 96.2%, $p < 0.0001$) [38] (Figure 97.5). If total T4 levels fall below 4 μg/dL, the probability of death is about 50%; with serum T4 levels below 2 μg/dL, the probability of death reaches about 80%. Reasons for poor prognosis associated with ETS remain unclear, but it has been suggested that ETS may be a reflection of global hormonal dysregulation within the context of severely deranged homeostasis, and also the fact that the occurrence of ETS may be an independent prognosticator in itself.

Although controversy exists as to whether or not the age at transplantation is associated with an increased risk of thyroid dysfunction, several compelling studies cite an age of less than 10 years as being a significant risk factor [34], whereas other studies have found no association.

Functional derangement of the thyroid post-HCT

Hypothyroidism of any type is the most frequent type of clinical or laboratory thyroid dysfunction seen in long-term survivors of HCT [34]; however, the incidence and time of onset for hypothyroidism requiring therapy are highly variable, depending on the type of pretransplant conditioning therapy applied. The median time to the diagnosis of hypothyroidism after HCT is nearly 4 years, while the cumulative incidence of overt hypothyroidism in 308 patients treated with loco-regional radiotherapy for non-thyroid head-and-neck cancer was 20% at 5 years and 27% at 10 years [39]. However, when hypothyroidism is defined as an elevation in serum TSH, the cumulative incidence is even higher, with 48% at 5 years and 67% at 8 years [40]. Other reports more modestly estimate the occurrence of subclinical hypothyroidism after allogeneic HCT to range from 7 to 15%.

The mechanisms by which hypothyroidism may develop post-HCT are unclear. As with thyroid dysfunction in general, a history of radiation exposure, particularly TBI, seems to be a significant risk factor [34]. Single-dose ablative TBI is associated with a 50% incidence of overt hypothyroidism, whereas fractionated TBI is associated with about 15%, compared with pretreatment regimens with BU–CY treatment alone, which represent approximately 11% of hypothyroid cases. The incidence of primary, symptomatic hypothyroidism after HCT without the use of TBI during the pretransplant conditioning regimen has been reported to be around 10–15% [38] (see Table 97.4).

Because hypothyroidism can occur with such relative frequency in HCT recipients who have not received radiation prior to transplant, non-radiotherapy-related mechanisms for post-HCT hypothyroidism have been proposed. Several cytokines regulate thyroid function, and these may be involved in the pathogenesis of thyroid disorders, including ETS. Additionally, the effect of conditioning chemotherapy and the graft-versus-host effect of infused lymphocytes may trigger human leukocyte antigen (HLA)-related AITD. The de novo development of autoimmune thyroid disorders, such as Hashimoto thyroiditis or Graves disease, has been reported in the presence of cGVHD or other pre-existing autoimmune dysfunction [41], although antithyroid autoantibodies occur more rarely than other autoantibodies with cGVHD [42]. While a limited number of case reports note the transfer of AITD from donor to recipient without any autoimmune phenomena by the mechanism of adoptive autoimmunity (i.e. the adoptive transfer of even a small number of pathogenic lymphoid clones) following allogeneic HCT [43], this type of adoptive transfer is likely a minor cause of autoimmune hypothyroidism, as most cases of post-HCT autoimmunity more likely result from an immunologic dysregulation (or "immunologic chaos") [44]. Although it is also possible for the remission of pre-existing autoimmune disease to occur after transplantation by the reverse mechanism, this has not been reported with respect to autoimmune thyroiditis, except for one case of Graves disease [45]. It has been suggested that up to 3% of the post-HCT population may suffer from autoimmune thyroiditis after 5 years of follow-up; meaning that the 5-year actuarial rates for autoimmune thyroiditis were 2.9 and 4% for allogeneic and autologous transplantation, respectively, which are very similar to the 2–4% lifetime risk of de novo autoimmune thyroiditis, which favors a female-to-male ratio of 3:1 [41], but the true incidence of clinically significant autoimmune thyroiditis after HCT remains unclear.

Presentation of functional thyroid derangement post-HCT

The diagnosis of functional thyroid disease after HCT depends on obtaining a careful history, a thorough search for the physical signs of hypothyroidism or thyrotoxicosis, and detailed evaluation of laboratory results.

While the onset of hypothyroidism may be insidious in the adult general population, after HCT disease development may be rapid, with frank manifestations of hypothyroidism present by 6 weeks, and myxedema by 3 months. The signs and symptoms of mild hypothyroidism may be quite subtle, variable, and non-specific, such as dry/coarse skin, cold intolerance, periorbital swelling, and a delayed ankle reflex relaxation phase. Unusual symptoms at presentation may include the following: neurasthenia with muscle cramps, paresthesias, and weaknesses; refractory anemia; disturbances in reproductive function, including infertility, delayed puberty, or menorrhagia; idiopathic edema or pleuropericardial effusions; retarded growth; obstipation; chronic rhinitis or hoarseness due to edema of the nasal mucosa or vocal cords; and severe depression progressing to emotional instability and even frank paranoid psychosis. Bone disorders related to hypothyroidism in children may include impairment of linear growth and waddling gait due to maldevelopment of the femoral epiphyses. Radiologic evidence of epiphyseal dysgenesis is virtually pathognomonic for hypothyroidism in infancy and childhood. Although the clinical picture of myxedema is usually clear in non-HCT recipients, it can often be difficult to observe in patients with GVHD of the skin post-HCT.

Hyperthyroidism of Graves disease may present with one or more of the following features: (1) thyrotoxicosis, (2) goiter, (3) ophthalmopathy (exophthalmos), and (4) dermopathy (pretibial myxedema). The clinical signs of hyperthyroidism in younger individuals include palpitations, nervousness, easy fatiguability, hyperkinesias, diarrhea, excessive sweating, intolerance of heat, and preference for cold temperatures, often with marked weight loss without a loss of appetite. Commonly seen manifestations are thyroid enlargement, thyrotoxic eye signs (e.g. ophthalmopathy), and mild tachycardia. Muscle weakness and loss of muscle mass may be severe. Rarely, thyroid dermopathy (thickening of the skin) and hypertrophic osteopathy (subperiosteal inflammation), particularly of the metacarpal and metatarsal bones, may be seen. In children, rapid growth with accelerated bone maturation occurs. In patients over 60 years old, cardiovascular and myopathic signs predominate, with the most common complaints being palpitation, dyspnea on exertion, tremor, nervousness, and weight loss.

Evaluation of functional thyroid derangement post-HCT

The diagnostic laboratory workup of hypo- or hyperthyroidism usually requires one or more of the following values: FT3, FT4, FT4I (FT4I, a calculation that can distinguish the level of T4 present compared with thyroid-binding globulin), and TSH (Figure 97.6). The combination of a low serum FT4 or FT4I and an elevated serum TSH is diagnostic of primary hypothyroidism, whereas the combination of elevated T4 and suppressed TSH confirms the diagnosis of hyperthyroidism. Suppression of both FT4 and TSH, in the absence of ETS suggests secondary hypothyroidsm related to pituitary or hypothalamic deficiencies.

Management of functional thyroid derangement post-HCT

Replacement doses of levothyroxine in adults range from 0.05 to 0.2 mg/day, with a mean of 0.125 mg/day, or 1.7 μg/kg/day. Dosage varies according to patient's age and body weight. In the elderly and in patients prone to cardiac problems, hormone replacement should be initiated at a low dosage (0.025 mg/day), and then be increased at 4–6-week intervals based on FT4 and TSH measurements up to a mean of approximately 1.6 μg/kg/day. Young children require a surprisingly high dose of levothyroxine compared with adults (e.g. 4–5 μg/kg/day in children aged 6–10 years versus 1–2 μg/kg/day in adults), and the initial dosage may be give at half the estimated final dose requirement for 4–6 weeks, and then adjusted based on FT4 and TSH according to the adult schedule. The major toxic symptoms of levothyroxine overdosage are those of hyperthyroidism, particularly cardiac complications (arrhythmia) and osteoporosis, in postmenopausal women.

Hyperthyroidism/Graves disease can be treated with radioactive iodine, antithyroid drugs (propylthiouracil or methimazole), or surgery (subtotal thyroidectomy), but in the Unites States, radioactive sodium iodide (I-131) at a dosage of 80–150 μCi/g thyroid weight estimated on the basis of physical examination and I-123 scan is the treatment of choice in patients without contraindications. The major complication of radioactive iodine is hypothyroidism, which ultimately develops in approximately 80% of patients who are adequately treated, and hormone replacement should begin as soon as hypothyroidism is confirmed. Patients with small, asymptomatic goiters can be monitored with clinical examination and periodic ultrasound evaluations.

Mass lesions of the thyroid post-HCT

In comparison with the general population, the incidence of thyroid nodules in survivors of HCT is fairly high. In one study, 26 of 95 (27.3%) patients who had received high-dose radiotherapy for childhood malignancies had palpable thyroid nodules 5–34 years after therapy [46]. Further, the incidence of nodules found in survivors of Hodgkin disease varies from 2 to 65%, depending on the length of follow-up and method of evaluation [47]. Because these populations are screened more often and more carefully, however, the true relative risk cannot be ascertained easily.

As with thyroid nodules, patients who underwent HCT during childhood harbor an increased risk of developing secondary thyroid carcinoma compared with the general healthy population (aged 0–29 years), with an overall reported incidence of 0.2% of children after HCT [48]. Factors that further increase the likelihood of malignancy are older age (about 45%), male gender (because nodules are less common in men, any given nodule in a male patient has a higher probability of being malignant), and family history of thyroid cancer (Table 97.6). A history of radiation exposure of the thyroid is significant, as irradiation causes subsequent hyperplasia, and thus a greater likelihood for the development of nodules and malignancies. The relative risk of inducing thyroid cancer is estimated as 0.6–14.9 after irradiation, but varies depending on several parameters: in particular, the use of TBI increases the relative risk to 3.6, versus 1.0 without TBI. The irradiation regimen used in HCT ranges from as low as 2–6 Gy up to 8–14 Gy in high-dose therapy. In comparison, as little as 6.5 cGy (1 cGy = 10^{-2} Gy = 1 rad) to the thyroid gland (e.g. during radiation treatment of tinea capitis) reportedly caused cancer in 0.11% of exposed children, versus 0.02% in sibling controls [49].

Increased doses of radiation exposure appear to correlate with a higher incidence of thyroid cancer, while exposure to extremely high doses of radiation (as much as 10,000 cGy) was rarely associated with the development of thyroid malignancy. This latter phenomenon is likely due to the fact that the thyroid gland is largely

destroyed by such high doses of radiation, and usually results in hypothyroidism. Notably, the presence or absence of GVHD does not appear to have a significant effect on the development of thyroid carcinoma post-HCT, although some studies have noted a higher relative risk in the presence of chronic GVHD [48].

Another risk factor for the development of secondary thyroid cancer after HCT is a younger age at the time of transplantation, with children 0–9 years old having a relative risk of 12.2 compared with 1.0 between the ages of 10 and 16 years.

Evaluation of mass lesions of the thyroid post-HCT

All patients who have received irradiation, including TBI, should be followed for life with physical evaluations 6 months after HCT, and then annually thereafter, including careful examination of the neck for goiter or nodules, and thyroid function studies (e.g. free T4 with or without TSH to rule out hypothyroidism) 6 months after HCT and annually thereafter. Notably, serum levels of thyroid hormones do not distinguish benign from malignant mass lesions of the thyroid, but may help to establish the presence of a functional thyroid lesion (hyperfunctioning thyroid nodules, also known as Plummer disease), or may reflect hypothyroidism in association with multinodular thyroid goiter or Hashimoto thyroiditis.

If a thyroid nodule >1.0 cm in diameter is found, the workup to rule out malignancy should include a TSH level and fine-needle aspiration (FNA) of the nodule for cytologic assessment and thyroglobulin measurement in needle washout especially if a lymph node is biopsied (Figure 97.7). FNA of thyroid nodules or suspicious neck lymph nodes can be performed blindly or under the guidance of ultrasound.

About 10% of FNA biopsies are inadequate and 20% are indeterminate. Genetic testing of the somatic mutation can be helpful for diagnosis and prognostication of the thyroid tumors, as multiple genes have recently been recognized to be involved in thyroid cancers. Although these mutations can be organized into eight categories, three are most commonly described: BRAF mutation, RET/PTC fusion, and Pax8/PPAR-gamma fusion, all of which converge at the matrix–metalloproteinase pathway associated with invasion and metastasis. The activating mutation in the gene encoding BRAF is the most commonly identified oncogenic abnormality in papillary thyroid carcinoma. In vitro and in vivo models have demonstrated that overexpression of activated BRAF induces malignant

Table 97.6 Clinical presentation of solitary thyroid nodule (>1 cm diameter) suspicious for malignancy

Factors increasing suspicion of thyroid carcinoma:
- ❑ Age <15 years or >45 years
- ❑ Male gender
- ❑ Nodule >4 cm in diameter
- ❑ History of radiation exposure
- ❑ History of diseases associated with thyroid cancer
  - – Pheochromocytoma
  - – Hyperparathyroidism
  - – Gardner syndrome
  - – Familial adenomatous polyposis
  - – Carney complex
  - – Cowden syndrome
- ❑ Suspicious criteria by ultrasound
  - – Central hypervascularity
  - – Irregular border
  - – Microcalcification
- ❑ Incidental focal PET-positive lesion in thyroid

Highly suspicious for thyroid carcinoma if present:
- ❑ Rapid nodule growth (over weeks to months)
- ❑ Very firm nodule
- ❑ Fixed nodule (to adjacent structures)
- ❑ Family history of thyroid cancer

- ❑ Enlarged regional lymph nodes (particularly low anterior cervical)
- ❑ Symptoms of invasion into neck structures (architectural distortion, e.g. tracheal deviation, muscle involvement, tumor fixation, difficulty swallowing, blockage of internal carotid artery)

transformation and clinically aggressive tumor behavior through constitutive activation, causing a phosphorylation cascade that leads to thyrocyte proliferation along with the loss of differentiation. The BRAF V600E mutation is associated with the presence of extrathyroidal extension and higher clinical stage, and correlates with the worst outcome (persistent disease and lower survival rate). The majority of indeterminate aspirates are of follicular origin, which do not harbor the BRAF V600E mutation; however, detection of the BRAF mutation in an indeterminate sample has 100% specificity and 58% sensitivity for the diagnosis of papillary thyroid carcinoma. The chimeric Pax8/PPAR-gamma gene frequently generates a chromosomal translocation in thyroid follicular carcinoma, but is absent in papillary carcinoma and Hurtle cell carcinoma. Activation of the RET gene via chromosomal rearrangement has been known for almost two decades to be associated with papillary thyroid carcinoma; its two most common variants are RET/PTC1 and RET/PTC3. The prevalence of RET/PTC is higher in patients with a history of radiation exposure, including those subjected to accidental or therapeutic radiation. For example, RET/PTC was present in the majority of thyroid cancer cases in child survivors of the Chernobyl accident. Hence there is clinical relevance in performing genetic analysis of indeterminate FNA aspirates in order to predict tumor behavior. Similarly, targeted disruption of the mutation product (e.g. auto-active BRAF kinase), could serve a therapeutic purpose in halting tumor progression.

A radionuclide thyroid scan can also prove useful in the case of nodules with indeterminate cytology results, as hyperfunctional nodules are almost always benign and can be managed medically with radioactive iodine or surgery. Thus, a radionuclide thyroid scan can assist in evaluating regional uptake or function within the thyroid gland, and is capable of localizing the presence of ectopic thyroid tissue. The radioactive tracers used for thyroid scans are isotopes of iodine (I-131 or I-123) or technetium (Tc-99m). Technetium scanning may be preferred at some diagnostic centers because it can be administered just 2 hours before the study. I-123 tends to be used for thyroid uptake tests and routine thyroid scans, and I-131 is reserved for follow-up evaluations of known thyroid cancer patients, owing to its higher radiation burden.

A normal scan indicates that the iodine uptake is similar in both lobes of the thyroid gland. Nodules may be classified as “cold” (decreased uptake), “warm” (uptake similar to that of surrounding tissue), or “hot” (increased uptake). Although a large proportion of thyroid nodules may be cold on radionuclide scan, only 5–15% of these are malignant in the general population; however, data from several large series suggest that the incidence of cancer in a patient with a history of therapeutic radiation of the head, neck, or chest who presents with a solitary cold thyroid nodule is as great as 50%.

Although MRI is not a primary diagnostic modality in the assessment of patients with thyroid nodules, nodules are often found incidentally during MRI of the neck for non-endocrine indications. The same is true of computed tomography (CT).

With the frequent use of positron emission tomography (PET) in patients with lymphoma and other cancers, an incidental finding of a localized [^{18}F]fluoro-2-deoxy-D-glucose (FDG)-positive lesion in the thyroid gland is associated with one-third of malignancies [50].

Metabolic and electrolyte abnormalities

Patients undergoing HCT are prone to the development of a wide variety of metabolic abnormalities, most of which occur during the early post-transplant period and may vary in severity from mild to life-threatening [51].

One study of 311 patients [51] reviewed the incidence of several metabolic/electrolyte abnormalities following HCT, demonstrating that a high number (269, 86.5%) of patients developed at least one severe metabolic abnormality within 100 days after allogeneic HCT. In all, 196 patients (63.0%) experienced one to three different metabolic abnormalities, whereas 73 (23.5%) had four to seven abnormalities. The most common abnormalities experienced within 100 days after HCT were hyponatremia (185, 59.5%), hypokalemia (149, 47.9%), hypophosphatemia (105, 33.8%), and hypomagnesemia (52, 16.7%). Less frequently encountered abnormalities were hyperkalemia (25, 8.0%), hyperuricemia (22, 7.1%), hypernatremia (13, 4.2%), and hypermagnesemia (9, 2.9%). Calcium abnormalities were found to be relatively rare, with hypercalcemia observed in one patient (0.3%) and hypocalcemia in one other patient (0.3%). One of the unique aspects of children with osteopetrosis undergoing allogeneic BMT is the development of hypercalcemia after bone marrow transplant, which needs to be treated promptly with hydration, furosemide, intravenous bisphosphonates, phosphate, and calcitonin [52]. In addition to these electrolyte abnormalities, derangements in glucose and lipid homeostasis were observed, with hyperglycemia being most common (138, 44.4%), followed by hypoglycemia (12, 3.9%), and hypercholesterolemia (3, 1.0%).

Induction regimens, immune suppression drugs, GVHD, and/or total parenteral nutrition (TPN) supportive therapy of patients undergoing or following HCT are among the factors contributing to the development of the metabolic and electrolyte disturbances seen. For example, the use of cyclosporine and tacrolimus in the prophylaxis and treatment of GVHD has been associated with hyperkalemia, hyperglycemia, hypomagnesemia, and hypertriglyceridemia in HCT recipients. As mentioned elsewhere in this chapter, glucocorticoid therapy may also cause hyperglycemia. GVHD-related gastrointestinal complications may also further the development of metabolic abnormalities. The subsequent occurrence of severe inflammatory or infective processes may lead to

insulin resistance by increasing levels of tumor necrosis factor-alpha (TNF-α). Long-term treatment with aminoglycoside antibiotics and amphotericin B with concomitant hypomagnesemia and vomiting can cause renal potassium wasting and hypokalemia. Pentamidine, used for the prevention or treatment of pneumocystis pneumonitis, may cause acute release of insulin due to pancreatic beta-cell damage, resulting in severe hypoglycemia followed by hyperglycemia. There was also a case report of hypoglycemia induced by insulin receptor antibodies following HCT [53]. Increased phosphate uptake by replicating neutrophils during the peri-engraftment period may additionally lead to hypophosphatemia in HCT recipients [54].

The occurrence of severe metabolic abnormalities following HCT tends to be associated with inferior clinical outcomes, and the impact of these metabolic disorders may be independent of other complications, including GVHD and hepatic sinusoidal obstructive syndrome (SOS) [51], suggesting that metabolic abnormalities that develop during the early post-transplant period may serve as prognostic indicators for patients undergoing allogeneic HCT. Thus, metabolic parameters should be closely monitored in patients treated with HCT.

In the following section, only HCT-associated hyponatremia will be discussed in detail. The diagnosis and treatment of other electrolyte abnormalities are usually more straightforward and therefore will not be addressed further.

Abnormal water metabolism

Hyponatremia, defined as a decrease in serum sodium concentration to ≤135 mmol/L, is a common electrolyte disorder in hospitalized patients, and is among the metabolic disturbances frequently encountered in oncology. Current data concerning the incidence of hyponatremia following HCT are limited, although one study reported the incidence to be as high as 40% [55]. Risk factors for hyponatremia following HCT include the development of syndrome of inappropriate antidiuretic hormone secretion (SIADH), hypothyroidism, adrenal insufficiency subsequent to discontinuation of glucocorticoid use, chemotherapy, treatment-induced nausea and vomiting, overhydration, pain, narcotic drugs, diarrhea, infection, renal failure, and physical and emotional stress. Diarrhea, in particular, is a relatively frequent complication of HCT because of mucosal damage, infection, and acute GVHD, and hyponatremia due to diarrhea is, therefore, frequently observed following HCT [51].

SIADH is another important, common cause of hyponatremia following HCT, and may result from cytotoxicity to paraventricular and supraoptic neurons (see below) as a side effect of conditioning therapy, especially with cyclophosphamide [51]. The presence of abnormal secretory stimuli, such as intrathoracic infection or the use of positive-pressure ventilation, may also cause SIADH. Inappropriate release of antidiuretic hormone (ADH) leads to retention of free water and hyponatremia. Thus, SIADH is characterized by hyponatremia, low serum osmolality, and an inappropriately high urine osmolality in the absence of diuretics, heart failure, cirrhosis, adrenal insufficiency, and hypothyroidism.

The rate of occurrence of SIADH, which was found in 16 (11.4%) of 140 HCT patients in one study, was unexpectedly high [55]. SIADH has also been associated with several hematologic diseases, such as non-Hodgkin lymphoma (NHL) and Hodgkin disease, although the most common cause of SIADH in NHL is thought to be the use of either vinca alkaloid-containing chemotherapy (see below) or direct invasion into the pituitary gland. The use of an HLA-mismatched donor may be a risk factor for SIADH, as is younger age at transplantation. Because the water content of young children is relatively higher than that of adults, electrolyte imbalances – and, correspondingly, SIADH – may occur more readily in a pediatric patient population. Further, the consequences of acute hyponatremia are more serious in young children.

SIADH-associated hyponatremia has been observed with the use of various antineoplastic agents due to chemotherapy-induced hypothalamic or posterior pituitary damage. Vinca alkaloids (vincristine, vinblastine) are thought to induce SIADH due to paraventricular or supraoptic cell microtubular damage. Vincristine additionally causes gastrointestinal sodium and water loss, resulting in appropriate ADH secretion. When vincristine is used in combination with cyclophosphamide, doxorubicin, methotrexate, and prednisolone (CHOP-M), the incidence of hyponatremia is about 17% [56]. In another series in which high-dose vinblastine, cisplatin, and bleomycin therapy were combined, eight of 12 patients developed hyponatremia and hypoosmolality [57].

High-dose cyclophosphamide therapy causes SIADH via a primarily direct effect on the hypothalamus. Post-mortem examination of a case of fatal cyclophosphamide-induced (1800 mg/m^2) hyponatremia revealed infundibular necrosis, decreased intra-axonal secretory granules, and depletion of posterior pituitary ADH [58]. Other mechanisms have also been invoked: in a small series of 19 chemotherapy courses with lower dosages of cyclophosphamide, there was development of hyponatremia, plasma hypotonicity, and urinary hypertonicity without an increase in plasma ADH levels [59]. This suggests that damage to the renal tubules and resultant defects of salt and water transport are the major cause of hyponatremia associated with low-dose therapy.

The mechanism of cisplatin-induced hyponatremia is unclear, but the renal toxic effects of cisplatin, rather than a direct effect on ADH secretion, are probably the major factor. This drug likely induces renal salt wasting, leading to hyponatremia, hypoosmolality, elevated urinary sodium, and urinary osmolality. Such an SIADH-like syndrome is difficult to distinguish from true SIADH when signs and symptoms of fluid volume depletion are subtle or absent.

It is not clear if melphalan has a direct effect on the development of hyponatremia or if it merely potentiates the effects of other agents. Melphalan-induced hyponatremia and urinary sodium loss, thought to be SIADH, have been reported in two patients who received high-dose melphalan (2 mg/kg) in combination with vincristine and cyclophosphamide [60]. Melphalan was implicated in the causation because challenge with the same regimen but a lower dose of melphalan (0.5 mg/kg) in one patient several weeks later did not cause hyponatremia.

Although not directly related to HCT, the presence of solid tumors may also be responsible for hyponatremia, either through ectopic secretion of ADH by the tumor itself, or through secretion of atrial natriuretic peptide, which causes renal salt wasting.

Among tyrosine kinase inhibitors, imatinib has been reported to cause SIADH [61]. The use of newer tyrosine kinase inhibitors, however, has not reportedly been associated with SIADH, but rather hyponatremia, of which cediranib had the highest (29%) risk of hyponatremia [62], versus patients on axitinib, who had a 9% risk of hyponatremia [63].

Evaluation of abnormal water metabolism post-HCT

As the clinical presentation may be highly variable and dependent on the cause, degree, and the chronicity of hyponatremia, the evaluation of these patients should be directed toward identifying the particular cause of hyponatremia (Figure 97.8) [64]. Establishing the hydration status of the patient is a significant first step. A history of fluid loss (e.g. vomiting, diarrhea, diuretic therapy) or one that is consistent with the development of SIADH, such as intake of an offending drug (see above), should be elucidated. On physical examination, pulmonary rales, S_3 gallop, jugular venous distention, peripheral edema, or ascites suggest hypervolemic hyponatremia. Dry mucous membranes, tachycardia, diminished skin turgor, and orthostasis suggest hypovolemic hyponatremia. Patients who lack findings of hypovolemia or hypervolemia are considered to have euvolemic hyponatremia, although identification of subtle degrees of volume depletion or edema may be difficult. As a result, laboratory testing is almost always required to establish the diagnosis of hyponatremia. Nevertheless, a history of corticosteroid use, or signs and symptoms suggestive of adrenal insufficiency or hypothyroidism, and also other metabolic abnormalities commonly observed post-HCT, such as hyperglycemia, hyperlipidemia, and hyperuricemia, should not be neglected. Other non-specific signs include muscle weakness and cramping; rhabdomyolysis is an occasional consequence of hyponatremia, and should be considered in patients with muscle pain or tenderness.

Standard laboratory testing for the evaluation of hyponatremia should include a chemistry panel, plasma osmolality, urine osmolality, and urine sodium concentration. Most cases of hyponatremia are associated with reduced plasma osmolality, but plasma osmolality may be normal, or even high, in hyponatremia that occurs in association with hyperlipidemia or hyperproteinemia, renal failure, hyperglycemia, or after the infusion of sucrose and maltose-containing immunoglobulin g (IgG) formulations. A urine osmolality of >100 mosmol/kg is consistent with an inability to excrete free water normally, which is generally due to continued secretion of ADH. A urine osmolality of <100 mosmol/kg may be due to primary polydipsia, malnutrition, or a reset osmostat. The urine sodium concentration is used to help distinguish between effective volume depletion and other causes in which euvolemia or renal salt wasting is present, and should be less than 20 meq/L with hypovolemia, unless salt wasting is occurring (e.g. adrenal

insufficiency). Urine sodium concentrations are generally above 40 meq/L in SIADH.

The diagnosis of SIADH is usually a diagnosis of exclusion, made from a combination of results from the history, physical examination (no edema), and laboratory tests, where the following results are generally observed: low plasma osmolality, an inappropriately elevated urine osmolality (above 100 and usually above 300 mosmol/kg), a urine sodium concentration usually above 40 meq/L, low blood urea nitrogen (BUN) and serum uric acid concentration, a relatively normal plasma creatinine concentration, normal acid–base and potassium balance, and normal adrenal and thyroid function. Patients with SIADH may have a low urine sodium concentration if they are also volume depleted, or if their sodium intake is extremely low. In such patients, the diagnosis of SIADH is made by observing the response to a saline load: the urine sodium rises but the urine osmolality remains high.

In patients for whom the diagnosis is not apparent after the initial evaluation, measurement of the plasma uric acid and urea concentrations, the fractional excretion of sodium, and adrenal and thyroid function tests may be helpful.

Management of abnormal water metabolism post-HCT

The choice of therapy is primarily governed by the cause and severity of the hyponatremia. Treatment should be directed first towards correcting any underlying causes of hyponatremia, such as cessation of a drug that induces SIADH, glucocorticoid or thyroid hormone replacement in patients with adrenal insufficiency or hypothyroidism, and control of hyperlipidemia and/or hyperglycemia. In these circumstances, the rate of correction of the underlying condition results in a relatively slow correction of the hyponatremia.

Rapid correction of hyponatremia is generally not indicated in asymptomatic hospitalized patients, particularly if the baseline plasma sodium is above 120 meq/L. Such patients are treated conservatively with free water restriction (e.g. restriction to 50–60% of daily fluid requirements to induce a negative water balance). If correction of volume depletion is indicated, intravenous isotonic saline and/or increased dietary salt (NaCl, 2–3 g/day) is administered. Salt therapy is usually contraindicated in edematous patients (e.g. heart failure, cirrhosis, renal failure) since it will exacerbate the presence of cerebral edema. Notably, the response to isotonic saline differs in states of volume depletion and SIADH. Isotonic saline is typically sufficient in true volume depletion, but ineffective in SIADH. Hypertonic saline is recommended only for patients with symptomatic or severe hyponatremia. To avoid the possibility of overcorrection, the therapeutic goal over the first 24 hours should be to increase serum Na^+ by 8 meq/L, with a maximum rate of correction of ≤10–12 meq/L in the first 24 hours, and ≤18 meq/L over 48 hours.

If the cause of SIADH cannot be corrected, and if water restriction is poorly tolerated or ineffective, demeclocycline (a tetracycline antibiotic that increases electrolyte-free water excretion by inhibiting ADH-mediated water reabsorption in the collecting duct) 300–600 mg in divided doses can be used. If the thirst sensation is intact, patients treated with demeclocycline rarely become hypernatremic. This drug is contraindicated, however, in patients with renal disease, hepatic cirrhosis, or congestive heart failure.

The arginine vasopressin (AVP)-receptor antagonists, a new class of agents, may correct hyponatremia by directly blocking the binding of AVP with its V2 receptors. V2 receptors are expressed in basolateral membranes of renal cortical and medullary collecting ducts and distal tubules. Binding of ADH to V2 receptor in the membranes of cells expressing the V2 receptor enhances production and trafficking of the water channel aquaporin 2 to the luminal membranes to facilitate water reabsorption into the hypertonic medullary interstitium to maintain plasma tonicity. By blocking the V2 receptor, the effect of ADH is blunted and the loss of water in the urine permits dilution of solutes in the urine and increase of urine osmolality. In clinical trials, conivaptan, lixivaptan, tolvaptan, and satavaptan have increased serum osmolality and normalized the serum $[Na^+]$ in hyponatremia associated with SIADH, cirrhosis, or congestive heart failure. These drugs may also have potential in cancer-related hyponatremia. At present, both intravenous conivaptan and oral tolvaptan are available, and are approved for the treatment of euvolemic hyponatremia (i.e. SIADH). The data that are currently available point towards easier management of hospital hyponatremia not only in the setting of SIADH, but also of hyponatremia associated with liver cirrhosis, nephrosis, and congestive heart failure, where the state of upregulated ADH is independent of serum osmolality.

Carbohydrate and lipid abnormalities

The prevalence of frank type 2 diabetes in HCT survivors appears to vary from 3.3 to 17% [65,66]. Impaired glucose tolerance was seen in 3.3–26% of adult patients treated with both TBI and non-TBI regimens prior to HCT. Hyperinsulinemia has also occurred post-HCT, with the highest insulin levels noted in patients receiving preparations of both cytotoxic drugs and TBI [67], but the connections between irradiation, busulfan, and insulin resistance are not clear.

Dyslipidemia of any type has been observed in approximately 27.9% of HCT recipients [65,66]. In general, of the several abnormalities in lipoprotein metabolism associated with insulin resistance, hypertriglyceridemia is the most common. A number of immunosuppressive medications have been documented to cause dyslipidemias, including cyclosporine, tacrolimus, sirolimus, mycophenolate, and high-dose administration of glucocorticoids. Glucocorticoids stimulate hepatic gluconeogenesis, diminish glucose utilization, oppose insulin action, increase protein breakdown, and activate lipolysis in the periphery; if patient insulin levels are inadequate to overcome insulin resistance and increased hepatic glucose output, steroid-induced diabetes mellitus will develop. Older age is a risk factor for steroid diabetes, and also for diabetes mellitus in general [68]. Iwamoto et al. did not find evidence for increased risk of long-lasting steroid-induced diabetes with cumulative doses of glucocorticoids [69], although long-term therapy has been associated with hypercholesterolemia.

It has also been shown that prolonged (4 days') ingestion and infusion of a hypercaloric carbohydrate diet (hyperalimentation) produced chronic elevations in both plasma insulin and glucose concentration, with plasma triglyceride (TG) concentration elevated fourfold compared with the values in the basal state [70]. The hyperalimentation formulas used post-HCT are often high in glucose and lipids, which may contribute to hyperglycemia, insulin resistance, and hyperlipidemia. Severe hyperglycemia early (first 10 days) post-allogeneic bone marrow transplantation has been shown to be associated with increased risk of acute GVHD in the following 90 days [71].

GVHD commonly affects the liver, first presenting with elevated liver transaminase levels, and then with intrahepatic cholestasis and dyslipidemia. This condition frequently manifests between 2 months and 2 years post-transplantation, and may occur in up to 40% of recipients from HLA-matched related donors [72].

Although few cases of severe hypercholesterolemia associated with GVHD of the liver in HCT patients have been reported in the literature, this clinical presentation may occur more frequently than previously perceived [73]. Consequently, there may be insufficient awareness of this important complication.

The patient's diagnosis at transplant was found to be the most significant risk factor for the development of type 2 diabetes post-HCT, with leukemic patients at greater risk than patients with other hematologic diseases, possibly due to greater exposure to pre-transplantation chemotherapy agents, and also to islet cell damage as the result of leukostasis or leukemic infiltration of the pancreas [67]. In this study, the prevalence of type 2 diabetes was found to be 9% among those with leukemia, versus 2% with aplastic anemia, compared with the prevalence of physician-diagnosed diabetes in the general population based on the 1988–1994 National Health and Nutrition Examination Surveys (NHANES) III survey: 1.1% among all 20–39-year-olds and 3.9% among all 40–49-year-olds. Additional evidence suggests that cancer survivors in general, and survivors of childhood acute lymphoblastic leukemia (ALL), are also at increased risk for metabolic syndrome [74].

Autoimmune type 1 diabetes may develop post-HCT due to the transfer of type 1 diabetes in a bone marrow allograft donor to a transplanted recipient, or because of recipient HLA susceptibility [67,75]. Further, as with type 2 diabetes, the prevalence of type 1 diabetes was approximately three times higher in HCT survivors than in the general population, at 0.52% versus 0.17% [67]. One case report, however, described a successful allograft for aplastic anemia in which the donor had type 1 diabetes at the time of transplant, but after a 21-year follow-up period, the recipient had not developed diabetes, although persistent antibodies were developed against pancreatic islet cells [76].

Pediatric HCT survivors seem more likely to develop either type 1 or type 2 diabetes than the general population [67]. Development of type 2 diabetes can also be causally related to the administration of GH therapy. In one study, GH therapy was associated with a significant sixfold increase in new cases of type 2 diabetes, including increases in insulin concentrations and other evidence of insulin resistance [77]. The occurrence of growth hormone deficiency itself may be a consequence of metabolic syndrome [74] (see the section on growth dysfunction).

Evaluation of carbohydrate and lipid abnormalities post-HCT

Clinical signs and symptoms of diabetes mellitus are related to the degree of hyperglycemia and the presence or absence of ketoacidosis or other hyperosmolar states, and may include polyuria, polydipsia, polyphagia, weight loss, and blurred vision, and may be associated with fluid and electrolyte disturbances, including elevated BUN and creatinine, low-normal or mildly reduced sodium levels, elevated serum potassium, low serum bicarbonate (<10 mg/dL), and elevated serum triglycerides. Uncomplicated presentations may reveal normal fluid and electrolyte measures, but if diabetic ketoacidosis is present, laboratory values will represent acidosis and more severe dehydration.

Management of carbohydrate and lipid abnormalities post-HCT

Regardless of whether or not the patient has a known history of diabetes, it should be emphasized that management of the hyperglycemic hospitalized patient must be intensive, particularly in the presence of severe illness. Acute metabolic derangements related to diabetic ketoacidosis (DKA) or hyperosmolar coma require urgent management in order to stabilize the patient and restore normal acid–base balance and volume status, and abrogate electrolyte abnormalities. Although hyperglycemia in itself may often be given secondary consideration in this setting relative to the development of other acute post-HCT complications, the onset and persistence of suboptimal glycemic control post-HCT could significantly prolong the length of hospital stay, and also increase the risk for morbidity and mortality.

The currently available classes of insulin preparations may be divided into (1) those intended for prandial use: regular insulin and rapid-acting insulin (lispro, aspart, and glulisine, onset of action within 1 hour or less), and (2) those for control of fasting blood glucose and background hyperglycemia: intermediate-acting insulin (NPH, onset of action within 1–3 hours and duration of action up to 24 hours, peak action at 6–8 hours) and long-acting insulin (glargine and detemir, peak action within 2–6 hours, duration up to 24 hours). In the acute care setting, continuous intravenous rapid-acting or regular insulin with frequent monitoring of plasma or serum glucose may be required in order to control hyperglycemia. Once stabilized, typical treatment may include multiple daily injections of premixed intermediate- and rapid-acting products, or freshly mixed or separately injected short- and intermediate-acting or long-acting preparations. The most serious complication of insulin replacement is that of hypoglycemia, the risk of which can be reduced in the inpatient setting by the careful monitoring and adjustment of insulin doses, and in the outpatient setting by teaching patients to recognize the signs of hypoglycemia, and also the measures that should be taken to reverse hyperglycemia once these symptoms are experienced.

Hyperalimentation with high lipid content is often prescribed in HCT patients, but in view of the potential metabolic complications from hyperlipidemia, particularly when combined with the presence of GVHD, hyperalimentation should be used for the shortest period possible, and oral or enteral feeding should be initiated as soon as is clinically feasible. Hyperlipidemia may also be seen as the result of GVHD of the liver. If such a patient with GVHD and hepatic damage is also receiving hyperalimentation, the lipid content should be reduced, and insulin may be given. Caution should be exercised when using the antihyperlipidemic medications in patients with hepatic damage, which can limit management options. Low doses of fibrates (i.e. amphipathic carboxylic acids for the treatment of hypercholesterolemia, such as gemfibrozil), niacin (vitamin B_3), and omega-3 fatty acids may be used, particularly when statins are contraindicated. Coenzyme Q10 (Co-Q10) may also be prescribed, but may have little to no therapeutic effects. Regardless of the treatment options utilized, liver enzymes should be closely monitored to avoid added hepatocellular toxicity related to the therapeutic agents themselves. Plasmapheresis may be employed in severe cases of hypertriglyceridemia to avoid pancreatitis.

Adrenal dysfunction

Cortisol secretion is tightly regulated by ACTH (Figure 97.9), and plasma levels of cortisol will parallel those of ACTH. The neuroendocrine mechanisms of the HPA axis normally permit (1) episodic secretion as related to circadian rhythms, and (2) cortisol secretion in large quantities in response to stressful stimuli. Endogenous glucocorticoids cause insulin resistance, increasing blood glucose concentrations via their actions on glycogen, protein, and lipid metabolism. Additionally, glucocorticoids can promote catabolic changes in muscle, skin, and connective tissue, inhibit osteoblast function, increase blood pressure, suppress immunologic responses, affect mood by increasing the manifestations of depression, euphoria, psychosis, apathy, and lethargy, increase the risk of peptic ulcer disease, inhibit linear skeletal growth, and suppress the thyroid axis.

Primary hypoadrenalism (Addison disease) is rare in the general population, with an estimated incidence of 0.8 cases per 100,000 [78]. As with the general population, transplant recipients have a low incidence of primary adrenal failure after HCT. Secondary hypoadrenalism, however, is fairly common. Although the adrenal gland is known to be relatively radioresistant, TBI has been implicated in adrenal

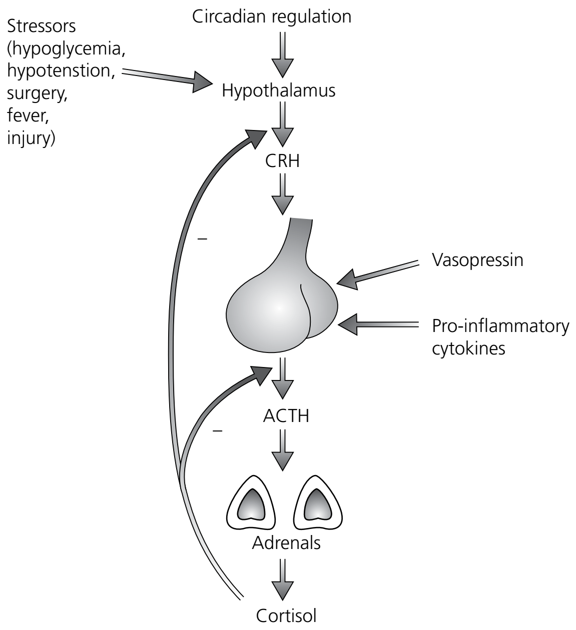

Figure 97.9 Neuroendocrine control of adrenal glucocorticoid secretion. Adrenocorticotropic hormone (ACTH) is secreted from the anterior pituitary under the influence of two principal secretagogues, corticotropin-releasing hormone (CRH) and arginine vasopressin; other factors, including cytokines, also play a role. CRH secretion is regulated by Circadian rhythm and additional stressors operating through the hypothalamus. Secretion of both CRH and ACTH is inhibited by cortisol, highlighting the importance of negative feedback control. Source: Stewart 2008 [78]. Reprinted with permission from Elsevier.

suppression post-HCT. Low-dose cranial irradiation, however, has not demonstrated disruption of spontaneous ACTH or cortisol secretion in several studies [2]. In general, however, secondary adrenal insufficiency is mainly the result of long-term, exogenous corticosteroid therapy, such as in HCT patients being treated for GVHD. Chronic administration of glucocorticoids suppresses the function of the HPA axis through a process that is dependent on both the dose and duration of treatment. Greater length and intensity of exposure are generally associated with a longer persistence of adrenal suppression; adrenal atrophy and subsequent deficiency should be anticipated in any patient who has taken more than the equivalent of 30 mg/day oral hydrocortisone (7.5 mg/day prednisolone or 0.75 mg/day dexamethasone) for more than 3 weeks [78]. High doses of glucocorticoids for as little as 3 days can also result in suppression of the HPA axis. The timing of the dose administration may also influence the severity of adrenal insufficiency, as larger evening doses will block circadian morning surges of endogenous ACTH. Because the HPA axis seems to remain intact, with any defects appearing to occur at the target organ level, adrenal function usually recovers gradually once exogenous corticosteroid exposure ends [2]. After chronic adrenal suppression has been established, however, sudden cessation of glucocorticoid therapy may result in adrenal crises, and care must be taken during steroid withdrawal. Failure to provide adequate glucocorticoid replacement in times of stress, such as with surgery or infection, may also precipitate deterioration in the general condition of the patient related to relative glucocorticoid deficiency.

The secretion of adrenal aldosterone is mainly mediated by angiotensin II, and also by ACTH and local potassium levels. Aldosterone acts on the kidneys to cause active reabsorption of sodium and passive reabsorption of water, and also the active secretion of potassium and protons in the collecting tubule, resulting in increases in blood pressure, blood volume, hypokalemia, and hyperchloremic metabolic alkalosis.

Adult adrenal androgen production is also regulated by ACTH. The most important adrenal androgens are dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS) and 4-androstene-3,17-dione. These hormones also exhibit circadian periodicity in synchrony with ACTH and cortisol, as plasma DHEA and androstenedione increase rapidly with ACTH administration, and are suppressed by the presence of glucocorticoids. Although the adrenal androgens have low androgenic activity, they can be converted into the potent androgens testosterone and 5α-dihydrotestosterone in both peripheral and target tissues. In normal males, this conversion accounts for less than 5% of testosterone, hence the physiologic effect is negligible. In contrast, adrenal androgens contribute to 50% or more of circulating, biologically active androgens in adult women; therefore, the adrenal glands may play important roles in the anabolic status and sexual function of females. Hence lack of DHEA and DHEAS in women may result in the loss of pubic and axillary hair and osteoporosis, and their excess will manifest with acne, hirsutism, and virilization. Thus, any HCT-related adrenal dysfunction is more likely to impact female patients. The significance of this postulation has yet to be clarified.

Evaluation of adrenal dysfunction post-HCT

Patients with primary adrenal failure usually will demonstrate signs of both glucocorticoid and mineralocorticoid deficiency. In both sexes, cortisol deficiency produces symptoms of weakness, fatigue, anorexia, nausea, vomiting, hypotension, hyponatremia, and hypoglycemia. Mineralocorticoid deficiency produces renal sodium wasting and potassium retention, and can lead to severe dehydration, hypotension, hyponatremia, hyperkalemia, and acidosis. Patients with secondary hypoadrenalism will have an intact renin–angiotensin–aldosterone system, which accounts for differences in clinical presentation between these two groups of patients with regard to salt and water balance. The most obvious feature that differentiates primary from secondary hypoadrenalism is the presence of hyperpigmentation of the skin and mucous membranes, which is not present in secondary forms of the disease.

Clinical suspicion should be confirmed with definitive diagnostic tests. Although a basal cortisol value >15 μg/dL normally suggests an intact HPA axis, low basal levels cannot be relied upon to exclude the diagnosis. Therefore, in practice, all patients suspected of having adrenal insufficiency should have an ACTH stimulation test [or Short Syntachten Test (SST)], which involves the administration of tetracosactin (which contains the first 24 amino acids of ACTH, and has the same physiologic properties) 250 μg IV or IM (Figure 97.10). Plasma cortisol levels are measured at 0 and 30 minutes after tetracosactin administration, and a normal response is defined by a peak plasma cortisol level >20 μg/dL. Incremental responses (i.e. the difference between peak and basal values) are of limited value other than determining the level of relative adrenal insufficiency. Response is unaffected by the time of day tested, and the test can still be performed in patients currently receiving corticosteroid replacement therapy, provided that the agent used is not measurable by that particular laboratory method, and the treatment is of short duration.

If necessary, there are several dynamic methods of differentiating primary from second hypoadrenalism. The first is the prolonged ACTH stimulation test (intravenous infusion of cosyntropin over

8 hours or over 24 hours on two or three consecutive days). In normal subjects, plasma cortisol will be >36 μg/dL after 4 hours of continuous infusion of cosyntropin, with no further increases observed over the remaining course of infusion. In primary adrenal insufficiency, no change is seen in cortisol or 17-hydroxycorticosteroid concentrations after prolonged ACTH stimulation. In secondary adrenal insufficiency, an incremental increase occurs during the course of the infusion, with much higher values observed at 24 and 48 hours than at 4 hours.

Many factors complicate the investigation of the HPA axis during critical illness, however. Cortisol levels vary greatly according to disease severity, and it may be difficult to define responses to testing. Decreases in corticosteroid-binding globulin (CBG) in the face of severe disease will alter the free to bound ratios of serum cortisol, further altering the results of testing. Some evidence suggests that a random cortisol value of <15 μg/dL is suggestive of corticosteroid insufficiency, whereas a level greater than 33 μg/dL would be unlikely to occur with compromised HPA axis function [78].

Management of adrenal dysfunction post-HCT

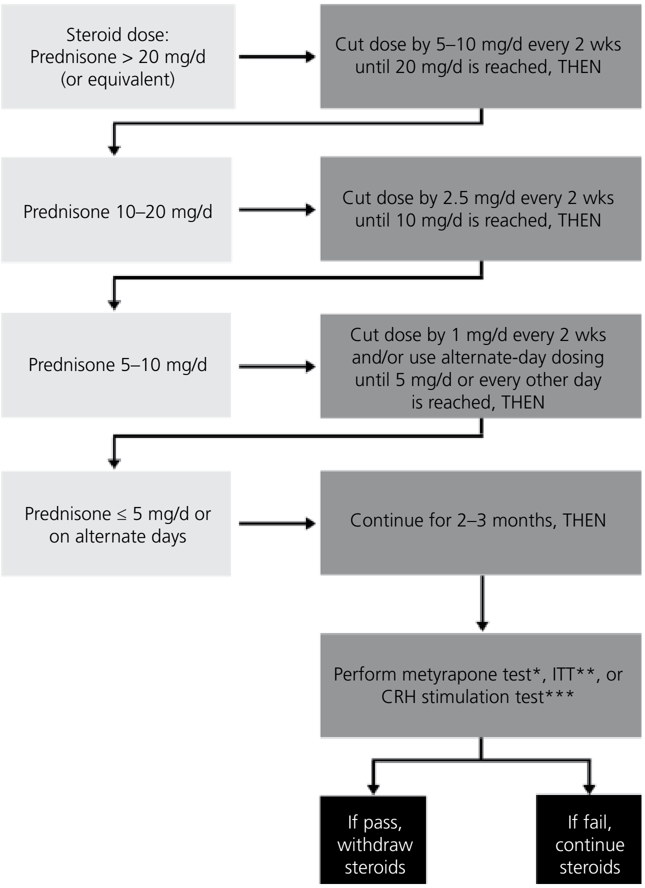
Clinically significant suppression of the HPA axis rarely occurs in patients who have taken steroid doses for less than 3 weeks' duration, and withdrawal of the steroids rarely causes any ill effects. HPA-axis suppression is inevitable, however, in patients taking the equivalent of 15 mg/day or more of prednisolone over the long term. Variable suppression of the HPA axis is seen with doses of prednisolone between 5 and 15 mg/day. To avoid the precipitation of adrenal failure, steroids should be withdrawn cautiously over a period of months (Figure 97.11).

All patients receiving long-term corticosteroid therapy should be treated similarly to patients with chronic ACTH deficiency. The aim is to give replacement doses of hydrocortisone to mimic normal cortisol secretion rates. Most patients are given hydrocortisone 15–25 mg/day in two doses, usually two-thirds in the morning and one-third in the evening. In the event of concurrent stressors, such as infection or surgery, supplemental steroid cover should be given, equivalent to 100–150 mg/day of hydrocortisone. Parental therapy may be required if the patient is unable to consume oral medications. In primary adrenal failure, mineralocorticoids also require replacement in the form of fludrocortisone 0.05–0.2 mg/day.

Administration of DHEA, normally secreted in large amounts by the adrenal glands, has been reported to have positive effects on the wellbeing and sexuality of women with adrenal insufficiency [80]. DHEA also increases bone density, muscle strength, and the sense of wellbeing in normal elderly men and women [81,82]. Prolonged high-dose glucocorticoid therapy may be a possible indication for DHEA therapy, especially in diseases that bear a high risk of osteoporosis [83].

Gonadal dysfunction

The provision of good quality of life in addition to the treatment of the primary disease has become an increasingly important goal, as life expectancy post-HCT continues to expand. Although the majority of young patients who have not yet had children themselves are concerned with subsequent fertility, a retrospective study conducted by the European Group for Blood and Marrow Transplantation (EGBMT), however, determined that the overall post-transplantation pregnancy rate is as low as 0.6% [84], indicating that HCT survivors rarely become parents [85]. Therefore, the high incidence of irreversible gonadal dysfunction observed after



Steroid dose:
Prednisone > 20 mg/d

If pass, withdraw steroids
If fail, continue steroids

Figure 97.11 Algorithm for steroid withdrawal for patients on glucocorticoid therapy of greater than 3 weeks' duration. Relative steroid potency (equivalence): 1 mg prednisone (or prednisolone) ≈ 4 mg cortisol or 5 mg cortisone; 1 mg dexamethasone ≈ 8–10 mg prednisone or 30–35 mg cortisol. *Overnight metyrapone test: 2–3 g (30 mg/kg) at bedtime, measure levels of 11-deoxycortisol, cortisol, and ACTH the following morning. Normal response: 11-deoxycortisol >7 μg/dL, ACTH >250 pg/mL; may compare cortisol level with baseline on previous day (expect inhibition). **ITT = insulin-induced hypoglycemia test: regular insulin 0.05–0.15 U/kg, intravenous push. Measure levels of ACTH and cortisol at 30-minute intervals for up to 2 hours. Physician must supervise. Normal response: cortisol >20 μg/dL, ACTH >250 pg/mL. ***CRH test = corticotropin-releasing hormone test: bovine or synthetic human CRH, 100 μg intravenous push. Measure ACTH and cortisol every 15–30 minutes up to 2 hours. Normal response: cortisol >13 μg/dL, ACTH peak level 10–120 pg/mL. Vasopressin may be administered to potentiate response to CRH.

Table 97.7 Risk factors for gonadal dysfunction following HCT

Female gender
Males undergoing allografted HCT
Older age at transplantation (particularly male patients, over the long term)
Use of TBI
Single-dose radiation
Cranial irradiation
Increased or cumulative doses of alkylating agents

allogeneic or autologous HCT has become a crucial issue for both male and female patients, as gonadal failure often results in incomplete sexual development at puberty (secondary sex characteristics), and a decrease in physical wellbeing, bone density, quality of life, and sterility and sexual dysfunction in adulthood.

Risk factors for the development of gonadal function post-HCT are given in Table 97.7, and the incidence of complications in Table 97.8.

Male

Most preparative conditioning regimens for HCT include high-dose combination alkylating agents and TBI, which are well known to induce gonadal dysfunction directly – namely, primary testicular failure (hypergonadotrophic hypogonadism), with a 50% reduction in testicular volume, severe germ cell injury, and even Leydig cell insufficiency [85]. Interestingly, Leydig cells are more resistant to both the toxic effects of chemotherapy and radiation (up to 24 Gy) than the germinal epithelium [86], which is completely destroyed at radiation doses of 8 Gy [87]. Although less common, gonadal dysfunction may also be initiated by central damage to the hypothalamic–pituitary region as a result of cranial irradiation, which causes impaired gonadotropin secretion; in children, this can lead to delayed onset of puberty, although premature sexual development may also occur in some cases. Hypopituitarism or hyperprolactinemia with subsequent hypogonadism has been reported in recipients of TBI, again reflecting radiation-induced hypothalamic defects. Although in one study the overall incidence of azoospermia after HCT was found to be 70.3%, the highest incidence of azoospermia following HCT was observed in patients prepared with cyclophosphamide (CY) plus TBI or thoracoabdominal irradiation (TAI) (85.4%), and recovery of spermatogenesis never occurred before the fourth year post-transplant, and as late as nine years [88].

Chemotherapy alone can also produce gonadal failure [37], as high-dose chemotherapy invariably provides direct insults to both germ cells and Leydig cells, with concomitant elevation in gonadotrophins. Further, a transient increase in sperm aneuploidy within 100 days after chemotherapy has been documented [88]. Previous administration of chemotherapy also has a cumulative effect on gonadal toxicity. Even monotherapy using a non-high-dose protocol, such as fludarabine alone, does not spare the gonads [85], although melphalan-based protocols are less gonadotoxic than TBI-based, BU–CY, or CY-alone regimens. Other drugs associated with germinal depletion include chlorambucil, nitrogen mustard, procarbazine, and nitrosoureas. Recovery of fertility, however, was found to be more likely after chemotherapy-alone conditioning regimens than after TBI-containing regimens [89], as recovery was seen in 90% of patients conditioned with CY alone, in 50% of patients with CY plus BU or thioTEPA, and in just 17% of patients with CY plus TBI or TAI (Figure 97.12).

Further, sperm quality was found to be within the normal range in the majority of patients following CY, whereas it was consistently severely impaired in patients who received irradiation or two alkylating agents [87]. Temporary falls in testosterone levels in the first 6 months post-transplant are thought to be insignificant.

A widely utilized non-TBI regimen prior to allografting is busulfan–cyclophosphamide (BU–CY), but when compared with BEAM (carmustine, etoposide, cytarabine, melphalan) and BECYM (carmustine, etoposide, cyclophosphamide, melphalan), it also appears to be the most toxic. Current recommendations after BU–CY have been to advise sexually active heterosexual male patients that spermatogenesis and fertility may occur within 2–5 years post-transplant; however, sperm cryopreservation prior to transplant is still recommended. In the minority of patients who remained persistently azoospermic at 5 years, semen analysis should be offered twice per year to detect late recovery.

In addition to the type of pre-transplant therapies employed, the degree of gonadal dysfunction after HCT is dependent on

patient-related factors. For example, older age at transplantation appears to worsen gonadal outcome after HCT in men; however, the majority of published studies describing the impact of high-dose chemotherapy plus TBI on gonadal function have evaluated patients who received transplants as adolescents or young adults. Although the data on gonadal function after HCT performed in childhood remain limited, most reports suggest that prepubertal boys experience spontaneous, normal puberty and sexual development, and further demonstrate age-appropriate plasma testosterone levels following HCT, indicating that younger male patient age at transplantation exerts a protective effect; some reports, however, showed impaired Leydig cell function in approximately half of boys who underwent HCT prior to puberty. The reasons for these differing results remain unclear, but could be related to variations in exposure to alkylating agents, and the total dose and/or fractionation schedule of irradiation. Other studies have suggested that the young Leydig cell, may have increased vulnerability to radiation-related damage, as evidenced by elevated luteinizing hormone (LH) levels, although overt Leydig cell failure was rare [87].

Germ cell dysfunction, as indicated by elevated follicle-stimulating hormone (FSH) levels, however, is more common [87], given the known sensitivity of the germinal epithelium to chemotherapy and radiation.

Long-term gonadotropin elevation after HCT despite prepubertal age at transplantation was thought to reflect a probability of future gonadal dysfunction (i.e. oligospermia and infertility) [87]; however, further studies are needed to support this conclusion.

The type of HCT itself also seems to exert an influence on gonadal outcome, since a higher incidence of gonadal toxicity (such as elevated FSH, indicative of seminiferous tubule damage, and elevated LH, indicative of Leydig cell damage) is more frequently seen in allogeneic than autologous transplantation.

The degree to which GVHD may contribute to or sustain gonadal toxicity independent of conditioning regimen remains to be evaluated, as sperm counts in long-term HCT survivors tend to be lower in GVHD patients. It has been suggested that intratesticular damage may occur during an acute graft-versus-host reaction due to infiltration of alloreactive donor T cells and autoantibody production against germinal epithelium. Evidence to support these hypotheses, however, is currently lacking. Additional studies are needed to clarify the role of GVHD in the development of gonadal dysfunction after HCT.

Evaluation of male gonadal dysfunction post-HCT

Semen analysis currently remains the only reliable method of assessing spermatogenesis.

In adult men, the most common symptoms of hypogonadism are diminished libido and erectile dysfunction (ED). Gynecomastia may also be a presenting feature; however, estimates of the incidence of gynecomastia in the general population are variable, and the incidence in the HCT setting is unknown. Primary testicular failure with hypergonadotrophic hypogonadism is likely the key cause of gynecomastia, but additional etiologies include secondary hypogonadism with hyperprolactinemia and drug-induced gynecomastia. For example, histamine (H2) blockers, such as cimetidine and ranitidine, are noted to be associated with sexual dysfunction and gynecomastia. Cyclosporine can cause transient breast enlargement through altered target organ sensitivity, but if present, it tends to be concurrent with hypertrichosis (not hirsutism). Although admittedly uncommon in recipients of high-dose chemotherapy or chemoradiotherapy, the occurrence of gynecomastia should be considered pathologic outside of newborns, puberty, and old age.

In general, gonadal testing and consideration for treatment are recommended based on symptoms (Figure 97.13). A male fertility evaluation should include a careful history and physical examination, and also a minimum of two semen analyses, which are recommended at the time of presentation, even if there has been less than 1 year of unprotected intercourse—particularly in the case of advanced female partner age (greater than 35 years), or the presence of known male risk factors (such as exposure to chemotherapy or radiation). Semen analysis is a common, convenient measure of assessing the male, and should precede any invasive tests of the female. Ejaculate volumes between 2 and 6 mL and sperm concentrations of greater than 15–20 million/mL with more than 50% motile sperm and more than 50% oval forms are considered normal.

Source: Adapted from Anunta and Kandeel FR 2007 [90].

An initial endocrine evaluation should include at least a plasma testosterone (T) and FSH, but frequently, LH is also included. This should be performed if there is (1) an abnormally low sperm concentration, especially if less than 10 million/mL, (2) impaired sexual function, or (3) other clinical findings suggestive of hypogonadism. A reduction in testosterone levels is usually a reflection of lower testosterone secretion by the testis. Elevated FSH typically indicates significant seminiferous tubule damage, and elevated LH indicates Leydig cell damage. If these hormone measurements are borderline, and the patient has clinical symptoms or signs of hypogonadism, then a free or bioavailable testosterone can be measured to exclude patients with low free T and elevated sex hormone-binding globulin (SHBG) as in elderly men.

Management of male gonadal dysfunction post-HCT

In its simplest form, the management of gonadal dysfunction following HCT should be directed at preventing potential damage by reducing injury wherever possible, such as with the use of less toxic conditioning regimens. TBI and alkylating agents should be avoided if possible.

Patients should be counseled prior to transplant to discuss possible and appropriate strategies to preserve fertility, including cryopreservation of sperm.

Failing preventive measures, hormone replacement therapy (HRT) may be offered to men to relieve some of the side effects of hypogonadism, and also for the preservation of bone mass density. In children, there are two phases to this treatment: a low dose to accelerate height growth during the growing period, without excessive bone-age progression, and then increasing the dose to the adult level at the end of the growth spurt. Sex steroid replacement therapy should be stopped for 2 months at regular intervals in order to check for gonadal recovery. Annual long-term follow-up is necessary, even for those few patients with normal hormonal basal values after HCT, owing to the possibility of future gonadal dysfunction due to diminished gonadal reserve.

The risks of HRT in men include prostate hypertrophy and prostate carcinoma. Side effects of treatment include edema, male pattern baldness, nausea, tachycardia, low HDL cholesterol, and cholestatic liver enzyme abnormalities. Follow-up evaluations should include annual digital rectal exams and measurements of prostate-specific antigen (PSA), liver function, lipid profile, and hemoglobin.

Female

Although the risk of gonadal failure is high in all individuals who undergo HCT, women generally experience higher rates of failure than do men; radiation doses as small as 4 Gy have been observed to destroy approximately 50% of oocytes [91]. As with men, women have a high risk of developing hypergonadotropic hypogonadism after HCT, but the risk of irreversible gonadal toxicity after BU–CY, with no resumption of menses, is almost inevitable in women.

In contrast, there is a higher incidence of fertility recovery in females than in males after TBI, BEAM, cyclophosphamide, BCNU, and etoposide (CBV), and high-dose melphalan. The greatest chance of recovery was observed in cases of non-high-dose therapy, e.g. mustine, vincristine, procarbazine, prednisone, or MOPP [mustargon, Oncovin (vincristine), prednisone, procarbazine], for Hodgkin disease. Similarly, the risk of permanent infertility becomes lower if cyclophosphamide is used alone.

In general, fractionation of radiation reduces the risk of infertility compared with single-dose radiation. Over the long term, when the use of fractionated TBI was considered alone, one study found that the ovaries are actually less sensitive to radiation than the testes are, with only 37% of females demonstrating permanent ovarian dysfunction more than 10 years after TBI administration, compared with 87% of males with at least indirect signs of germinal dysfunction [92].

Older age at HCT is associated with nearly 100% ovarian failure, likely due to the decreased number of primordial follicles. In general, endocrine ovarian failure is irreversible in adult women, but younger women – particularly prepubescent girls treated with chemotherapy and hyperfractionated TBI – have a better opportunity for recovery of gonadal function, and about half may experience spontaneous puberty and menarche. Whereas doses of 600 cGy may produce irreversible ovarian failure in women older than 40 years of age, doses in excess of 2000 cGy have to be given before the same result is seen in girls treated during childhood and adolescence. The parameter of age, however, seems to be less significant in female patients over the long term, as follow-up beyond 10 years has demonstrated a similar probability of ovarian dysfunction in females who were administered TBI prior to puberty as well as post-menarche [36]. Faraci et al. documented the development of amenorrhea in 100% of females receiving TBI at some time after puberty [36]. Some patients were able to recover from the injury, sometimes more than 10 years after TBI; this has been corroborated by other studies that demonstrated recovery of ovarian function in 10–25% of young women after TBI. Regardless of recovery, however, a higher risk of earlier menopause has been suggested with exposure to both alkylating agents and radiation below the diaphragm, even in girls treated during a prepubertal phase. It is unclear what allows some patients to remain fertile when so many other patients become sterile under similar conditions.

Shielding of the gonads is generally not performed after HCT, since the gonads often serve as sanctuaries for disease, particularly in lymphoid disorders such as ALL. Even if shielding is employed, it is less successful in preserving female fertility than male fertility. No effective means of protecting the ovaries during high-dose chemoradiotherapy has yet been developed.

In conclusion, larger studies are required in order to evaluate the incidence of recovery of fertility in females after various conditioning regimens and the effects of variables such as prior treatment and age at transplantation. Until these results become available, it is recommended that post-transplant ovarian function be evaluated in all premenopausal women prior to transplant, particularly if BU–CY will be used. Counseling regarding fertility preservation prior to transplant is necessary; options may include cryopreservation of fertilized embryos, ovarian tissue, and oocytes.

Fertility and offspring

Many animal studies have investigated the possible adverse effects of radiation and chemotherapy on the offspring of treated patients [88]. The risk of genotoxicity is more significant in cases when assisted reproductive technology (ART) with intracytoplasmic sperm injection (ICSI) is used. Although the incidence of congenital anomalies recorded in live-born infants spontaneously conceived after treatment for lymphohematologic malignancies is comparable to that reported in the general population [93], possible long-term radiation-related genetic damage of the spermatozoa and oocytes cannot be excluded [88]. Long-term follow-up of both pregnancies and children of HCT survivors is needed, particularly with regard to the occurrence of miscarriages, low birth weights, congenital malformations, and delayed developmental milestones [93], as the evidence seems to be conflicting. Holm et al. [94] were the first to report a reduction in both uterine and ovarian size shortly after TBI and HCT administered in female children, despite HRTy or spontaneous pubertal development, citing that prescribed doses of HRT, although sufficient to induce bleeding and suppress the onset of premature menopause, were not adequate to generate normal uterine growth; this is significant, as these smaller, irradiated uteri may not be able to grow and expand as required during pregnancy. Further, decreased ovarian volume was found to be reflective of decreased markers of ovarian follicles compared with ovarian follicles found in healthy females entering puberty; small ovaries have been associated with poor response to IVF.

Although there is a theoretical risk of immunocompromise and relapse, the fact of pregnancy is unlikely to alter the history of the primary disease, and is therefore not contraindicated in SCT recipients for hematologic, endometrial, or even breast cancers; however, scattered case reports have shown evidence of leukemic relapse during pregnancy, although it is unknown to what extent these patients were already at risk for recurrence independent of the pregnancy. Nevertheless, it is recommended that patients with CML should delay pregnancy for at least 2 years after HCT, provided that they remain Philadelphia chromosome- and bcr/abl transcriptase-negative.

Evaluation of female gonadal dysfunction post-HCT

Failure to progress through puberty in a timely fashion should prompt the referral for a full endocrinologic evaluation. Prepubertal girls should be monitored closely for the onset of puberty and gonadal dysfunction suspected if not experienced by the age of 12–13 years. In contrast, the association between premature sexual development and both low- and high-dose CNS irradiation in both boys and girls is now well established.

In adult women, the assessment of gonadal function after HCT is difficult, as the ovaries and ova are not easily accessible for study, and E2 levels are highly variable across individuals and even within the same individual. The implicit markers of female fertility are regular menses and the ability to become pregnant; however, the initial investigation should start by ruling out thyroid hormone abnormalities and the possibility of current early pregnancy. Once this has been achieved, then the pursuit of further evaluations will depend upon whether the patient is presenting with complaints of infertility or with oligomenorrhea and symptoms of estrogen deficiency (Figure 97.14). Patients presenting with infertility should be evaluated with measurement of serum inhibin B during the mid-follicular phase (days 5–8) and/or progesterone during the mid-luteal phase (days 19–22) of the menstrual cycle. Low inhibin B levels suggest poor ovarian follicular reserve, and low progesterone levels could indicate poor luteal phase function. Such subjects and those with oligomenorrhea should be further evaluated with measurements of serum E2, FSH, and prolactin. Ovarian failure is clinically represented by amenorrhea and menopausal symptoms, and also low levels of serum estrogen and high levels of serum FSH and normal or low levels of prolactin. In women presenting with decreased sexual libido (hypoactive sexual desire), serum levels of testosterone and DHEA should also be measured. Reduced serum levels of total and/or free testosterone may be associated with

ovarian failure and, in some cases, reduced DHEA levels may reflect adrenal insufficiency.

In vitro fertilization (IVF) using superovulation and embryo cryopreservation is a common treatment for infertility in female HCT recipients, as it has the most promising results, despite some limitations: requirements include the presence of a functional ovary and the time to complete the necessary number of IVF cycles to harvest sufficient eggs prior to the commencement of the cytotoxic regimen, which may be difficult to achieve in some patients without delaying life-saving treatment. Oocyte cryopreservation and gonadotropin-releasing hormone (GnRH) treatment for the suppression of the pituitary–gonadal axis remain more experimental treatments, and further studies are needed to ascertain their usefulness.

Management of female gonadal dysfunction post-HCT

As with men, the management of gonadal dysfunction following HCT in women should be aimed at preventing potential damage by reducing injury wherever possible, such as with the use of less toxic conditioning regimens. TBI and alkylating agents should be avoided if possible.

Patients should be counseled prior to transplant to discuss possible and appropriate strategies to preserve fertility, including cryopreservation of oocytes, ovaries, and embryos, and the use of a surrogate uterus.

As with men, HRT may be offered to females to relieve some of the side effects of hypogonadism, and also for the preservation of bone mass density. The phases of HRT in girls follow those of young boys, described above. In girls, however, the latter phase is given cyclically in order to induce regular menstruation. HRT may be given to stimulate normal uterine growth. Sex steroid replacement therapy should be stopped for 2 months at regular intervals in order to check for gonadal recovery. Annual long-term follow-up is necessary, even for those few patients with normal hormonal basal values after HCT, owing to the possibility of future gonadal dysfunction due to diminished gonadal reserve.

Sexual dysfunction

Although sexual dysfunction may be considered a secondary issue in comparison with the primary malignant disease, sexual activity is a major contributor to quality of life in these patients. HCT patients have been found to be similar to conventional chemotherapy patients with regard to psychosexual functioning, and both groups exhibited significant differences in all aspects of sexuality compared with healthy control subjects – particularly with regard to body image [95]. When given the opportunity, 35% of the sample detailed negative changes in sexual function after transplantation [96]. Wingard et al. reported that 22% of male HCT survivors were dissatisfied with their sexual lives, with 24% reporting ED and 13% ejaculatory dysfunction [97], whereas Molassiotis et al. noted that half of patients were sexually dissatisfied to some extent [98]. Across both sexes, lack of sexual interest is reported at 3–11%, arousal problems 9–15%, and orgasm infrequency or inability 4–12% [96]. Unmarried and single patients seem to be at greatest risk for sexual dissatisfaction [98], and women appear to be affected more frequently than men [99], with 17–35% reporting sexual problems [96].

Sexual difficulties in HCT survivors typically have acute onset, and occur immediately after therapy or during the recovery process as a result of physical gonadal dysfunction due to treatment with TBI and alkylating agents. Adrenal suppression by corticosteroids may also cause a reduction in DHEA levels. Sexuality may be further influenced by the occurrence of fatigue, decreased stamina, alopecia, skin changes due to GVHD, weight changes, anxiety, depression, cognitive interference, and other social changes. Other stress factors, such as financial, familial, or occupational concerns, may further contribute to sexual dysfunction.

Male

As noted above, male HCT survivors are typically less affected with regard to sexual function than female HCT survivors, and if affected, their problems appear to resolve spontaneously. One study noted that men who had no known sexual complaints prior to transplantation who did report sexual dysfunction at 1 year after transplant were found to be problem-free 3 years after transplant [96]. Only 15% of HCT patients in this study reported arousal problems prior to transplantation.

Evaluation of men with sexual dysfunction post-HCT

There are many reasons why HCT in particular may cause sexual dysfunction in male patients. The underlying hematologic disease (e.g. sickle cell anemia) may cause local penile abnormalities and subsequent ED (sickle cell), as can microvascular disease from treatment-associated complications, such as hyperlipidemia. Neuropathy as the result of TBI and chemotherapy or the development of diabetes may additionally cause sexual dysfunction. Glucocorticoid treatment may cause weakness and fatigue, and many other HCT-related pharmaceutical agents are known to cause sexual dysfunction. The development of psychologic issues related to self-esteem that are specific to HCT may precipitate dissatisfaction with one's sexual prowess and create partner discord, including despair regarding the underlying disease and its treatment, a resultant loss of work and livelihood, possible disfigurement due to GVHD of the skin, the loss of body/muscular mass, and the occurrence of new and unpleasant body odor related to medications.

Decreased libido should alert the clinician to three probable causes: endocrinopathy, affective disorder, or relationship discord. A history of frequent strong erections under any circumstances (during foreplay, fantasy or masturbation, with another partner, or upon awakening) likely indicates that the endocrine, vascular, and neurologic systems are intact, and that the ED is predominantly psychogenic. Conversely, historical data relating the presence of decreased erectile turgidity during non-coital activities are highly suggestive of an organic etiology. A report of firm sustained erections during foreplay that are lost after intromission or upon initiation of pelvic movements, however, might suggest either a psychogenic etiology or a vascular problem (pelvic steal syndrome). A history of delayed or retrograde ejaculation may imply a neuropathy or an adverse drug effect. Premature ejaculation, on the other hand, is more compatible with a psychogenic dysfunction. Finally, it must be remembered that the absence of orgasmic sensations in patients with normal erectile and ejaculatory functions is almost always due to psychogenic etiology, whereas failure of detumescence is usually organic in nature; the latter should direct investigations towards ruling out local penile etiologies (neurologic or hematologic) [100].

During the physical examination, every effort should be made to elicit physical signs of pathology that may be suspected based on information obtained during the clinical history. Evidence of chronic, systemic diseases (hepatic, renal, cardiovascular, endocrine, granulomatous, neoplastic) must be ruled out, and if present, the current state of disease control should be determined. In addition to the general and systemic evaluations, a detailed assessment of gonadal function, vascular competence, neurologic integrity, and genital organ normalcy should be performed on every patient.

Laboratory testing should focus on the endocrine aspects of male sexual dysfunction (i.e. the state of gonadal hormones and thyroid hormones), as these are particularly vulnerable to derangement after HCT (see Figure 97.13). Aging, growth hormone deficiency, hyperthyroidism, and liver disease can all be associated with an increase in SHBG, and consequently a greater reduction in bioavailable than in total testosterone. On the other hand, obesity, hyperinsulinemia, hypercortisolemia, and hypothyroidism may be associated with decreased SHBG and thus more suppression in total testosterone than in bioavailable or testosterone [100].

Management of men with sexual dysfunction post-HCT

As sexual dysfunction after HCT is frequently multifactorial in origin, these different etiologies should be distinguished, and treatment should given to address each of the underlying problems accordingly.

If hypogonadism is the cause, hormone replacement should be given (see the previous section). Androgen replacement therapy is usually not required with sexual dysfunction associated with normal bioavailable or free but depressed total testosterone. Phosphodiesterase-5 (PDE-5) inhibitors have been found to be very effective for men with ED in the general population. Several non-surgical treatment options for ED have proven to be safe and efficacious, regardless of disease etiology, and may prescribed in the primary care setting (e.g. oral or intraurethral medications and vacuum constriction devices) [101]. Antioxidant agents such as vitamin E, Korean red ginseng, and α-lipoic acid (ALA) have shown promise in animal studies, but human research is needed.

Psychiatric/psychosocial support may improve a patient's situation and allow for a better quality of life. Unmarried and single HCT survivors should be targeted for early prevention or therapy. Appropriate intervention will involve identifying and addressing all relevant predisposing, precipitating, and perpetuating factors, and thus evidence for the presence of any of these psychologic or situational conditions should be carefully assessed. Moreover, it should not be forgotten that the presence of an organic dysfunction does not preclude the possibility of a coexisting psychogenic factor, and vice versa. Such omissions could lead to diagnostic difficulties, and also to therapeutic failures.

Female

Sexual dysfunction in women treated with HCT may predate their treatment or occur de novo following therapy. In women without sexual problems prior to transplantation, up to 40% developed lubrication difficulty, problems achieving orgasm, and painful intercourse. Dysfunction is often pervasive and severe, and the problems did not seem to improve over time, but rather seemed to consolidate and generalize to other aspects of sexual function [96]. Of women with arousal difficulty prior to transplantation, 71% had this problem after 3 years, whereas 42% without arousal problems prior to transplant had developed it by 3 years after transplant. Particularly for women, if sexual problems were not prevented or resolved at 1 year after transplant, there was an 87% probability that the problems would still be present at 3 years after transplant, despite HRT; however, a substantial number (63%) of women entered transplantation with one or more sexual problems [96]. After HCT, specific sexual complaints in female survivors include dyspareunia (2–8%) and insufficient vaginal lubrication. Prevalence rates for these particular problems vary widely in the general population, depending on the sample.

As with male patients, self-image issues that arise out of the fact of HCT and its treatment may contribute significantly to decreased psychologic and sexual wellbeing.

Evaluation of women with sexual dysfunction post-HCT

In women, the onset of early menopause has been noted as a major cause of sexual dysfunction, including symptoms of vasomotor instability, vaginitis, dry vaginal mucosa, dysphoria, osteoporosis, hot flashes, insomnia, irritability, decreased libido, and vaginal atrophy [96]. The evaluation of gonadal function in women presenting with menstrual irregularities with estrogen deficiency symptoms should be carried out as described in Figure 97.14.

Several methods of testing for female sexual dysfunction exist, including instruments to measure the level of vaginal arousal, lubrication, and blood flow, but the use of these modalities is mainly limited to the research setting.

Management of women with sexual dysfunction post-HCT

Although there are fewer available treatment options for female sexual dysfunction than for ED, for example, a report suggests that sildenafil (Viagra) may improve sexual arousal disorder in premenopausal women [102]. Management of lower urinary tract syndrome (LUTS), such as bladder control/continence and the prevention and treatment of infections, can also improve sexual function for both men and women.

The treatment for gonadal dysfunction and possible infertility post-HCT may have a large impact on patient sexual behavior. It is recommended that counseling regarding the potential for reduced sexual satisfaction and other sexual difficulties should occur prior to transplantation. Clinicians should be aware of the additional possibility of late-occurring problems with psychosexual maladjustment post-HCT. HRT should be offered, although, as noted above, libido is only partially corrected by standard doses of estrogen and progesterone in women; further studies are needed to address the true endocrinologic requirements of these patients.

The needs of women who cannot take HRT, or those who choose not to take HRT, must also be addressed. Many alternative therapies (such as botanical products) are popularly recommended, but controlled clinical trials on their efficacy are entirely lacking. Improvised vaginal lubricants have been offered as a possible treatment.

As with male HCT survivors, psychiatric/psychosocial counseling may significantly improve self-esteem and quality of life.

Conclusion

The widespread implementation of HCT and increasing long-term survival rates have warranted greater concern with regard to long-term quality of life for transplanted patients. Endocrine complications of HCT are often notoriously late in onset, even manifesting decades after the initial transplant. Dysfunction of the endocrine system can severely impact both the morbidity and mortality of HCT recipients. It is hoped that awareness of the various types of endocrine complications of HCT and regular monitoring of transplant survivors for the signs and symptoms of these problems will further improve the long-term quality of life for HCT recipients.

CHAPTER 98

Common Potential Drug Interactions Following Hematopoietic Cell Transplantation

Anne Poon and Lowan K. Ly
University of Washington Medical Center, Seattle, WA, USA

Introduction

Drug interactions in hematopoietic cell transplantation (HCT) patients occur owing to the complexity of the medications employed, patients' comorbid conditions, and transplant complications. Often, the pharmacologic effectiveness or safety profile of one drug is altered by the concurrent administration of another drug, food, or herbal product. Pharmacokinetic, pharmacodynamic, and pharmaceutic interactions are possible.

Pharmacokinetic interactions occur when the addition of one drug leads to a change in the concentration of another. These may happen during the absorption, distribution, metabolism, and elimination phases of drug administration, with a majority of them occurring in the latter two phases [1]. Many factors affect a drug's pharmacokinetic profile, including route of administration, affinity for protein binding, and patient variables, such as age, ethnicity, and organ function. Pharmacodynamic interactions occur when two drugs of similar or opposing pharmacologic actions result in an altered (antagonistic, synergistic, or indirect) response by the body [2]. Pharmaceutic interactions occur as a result of chemical or physical incompatibilities [2]. Some pharmacokinetic interactions are beneficial whereas others are harmful. Knowledge of commonly encountered pharmacokinetic drug interactions is critical to mitigating any deleterious impact on HCT patients. These interactions, their management, and the pathways associated with them, such as the P-glycoprotein (P-gp), organic anion-transporting polypeptide (OATP), cytochrome P450 (CYP450) isoenzyme, and uridine 5′-diphosphate glucuronosyltransferase (UGT) systems are reviewed in this chapter. A brief discussion of the role of therapeutic drug monitoring (TDM) is also presented.

P-glycoprotein (P-gp) system

P-gp is an ATP-dependent plasma membrane transport system encoded by human multidrug resistance genes [1]. Originally discovered in cancer cells, P-gp is also found in normal human tissues, including the intestines, blood–brain barrier, placenta, liver, and kidney [3]. P-gp modulation plays an integral role in the overall systemic disposition of drugs. Drugs can be substrates, inhibitors, and inducers of P-gp. The net effect of P-gp-based interactions depends on the location of P-gp, the normal function of P-gp at that location, and a drug's overall effect or dependence on P-gp. In the gastrointestinal (GI) tract, blood–brain barrier, and placenta, P-gp normally functions as an efflux pump to limit drug entry, whereas in the liver and kidneys, it functions to promote drug removal [3]. P-gp-mediated drug interactions in the GI tract alter drug absorption whereas similar drug interactions in the liver and kidneys alter drug metabolism and excretion, thereby affecting the overall systemic concentration of drug in the bloodstream [4]. For example, with the administration of a P-gp substrate and inhibitor, systemic substrate concentrations are increased in the GI tract because normal P-gp function to limit cellular entry is inhibited whereas with P-gp inducers, systemic substrate concentrations are reduced since normal P-gp function to limit cellular entry is enhanced [4,5]. Similar outcomes in terms of systemic substrate concentrations are seen when enzyme inhibition or induction occurs in the liver and kidneys, whereby administration of P-gp inhibitors increases systemic bioavailability of P-gp substrates through decreased metabolism and reduced excretion whereas inducers do the opposite [5]. The extent of these interactions is unpredictable, especially when multiple P-gp substrates, inhibitors, or inducers are administered. Additionally, since drugs, especially those with extensive first-pass metabolism, must go through the liver prior to its entry into systemic blood circulation, they are further susceptible to the effects of other drugs that alter the enzymatic environment within the liver. This also applies to P-gp-mediated interactions since P-gp is more concentrated in the liver [6]. Commonly encountered P-gp substrates in HCT include fentanyl, morphine, ondansetron, phenytoin, and methylprednisolone. Azole antifungals, atorvastatin, and midazolam are examples of P-gp inhibitors and rifampin, phenytoin, and insulin are examples of P-gp inducers. Some drugs, such as amiodarone and sirolimus, can inhibit and induce P-gp. Erythromycin, calcineurin inhibitors, and diltiazem are P-gp substrates and can also inhibit and induce P-gp [5].

Organic Anion-Transporting Polypeptide (OATP) system

Like P-gp, OATP is a transport system found in the GI tract, brain, liver, and placenta [7]. In contrast, OATP is a drug influx pump, transporting drugs intracellularly. Human OATP consists of 11 members; the roles of OATP1B1, OATP1A2, OATP1B3, and OATP2B1 are best characterized. OATP1A2 facilitates drug entry from the duodenum into circulation whereas OATP1B1, OATP1B3, and OATP2B1 mediate the transport of drug from the circulation into hepatocytes for metabolism and elimination [8]. Modulation

Table 98.1 Selected CYP isoenzymes and common inducers, inhibitors, and substrates [1,9,10]

Isoenzyme	Inducers	Inhibitors	Substrates
CYP1A2	Insulin, omeprazole, phenobarbital, phenytoin, rifampin, tobacco	Amiodarone, cimetidine, ciprofloxacin, erythromycin, fluoxetine, grapefruit juice, paroxetine, sertraline	Amitriptyline, caffeine, duloxetine, haloperidol, mirtazapine, ondansetron, propranolol, verapamil, (*R*)-warfarin
CYP2B6	Phenobarbital, rifampin	ThioTEPA	Bupropion
CYP2C9	Phenobarbital, rifampin	Amiodarone, fluconazole, fluoxetine, fluvastatin, isoniazid, itraconazole, ketoconazole, lovastatin, metronidazole, paroxetine, sertraline, trimethoprim, voriconazole	Fluoxetine, fluvastatin, NSAIDs, phenytoin, sertraline, voriconazole, (*S*)-warfarin
CYP2C19	Carbamazepine, norethindrone, phenobarbital, prednisone, rifampin	Cimetidine, fluoxetine, ketoconazole, lansoprazole, omeprazole, sertraline, voriconazole	Citalopram, cyclophosphamide, diazepam, escitalopram, omeprazole, phenobarbital, phenytoin, sertraline, voriconazole
CYP2D6	Dexamethasone, rifampin	Amiodarone, bupropion, cimetidine, citalopram, duloxetine, escitalopram, fluoxetine, haloperidol, metoclopramide, mirtazapine, paroxetine, sertraline, venlafaxine	Citalopram, duloxetine, escitalopram, fluoxetine, haloperidol, metoclopramide, metoprolol, mirtazapine, ondansetron, paroxetine, venlafaxine
CYP2E1	Ethanol, isoniazid		Acetaminophen, ethanol
CYP3A4/5	Barbiturates, carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin	Amiodarone, cimetidine, ciprofloxacin, clarithromycin, diltiazem, erythromycin, fluconazole, fluvoxamine, grapefruit juice, itraconazole, ketoconazole, verapamil, voriconazole	Alprazolam, amiodarone, amlodipine, atorvastatin, clarithromycin, cyclosporine, dasatinib, diazepam, diltiazem, erythromycin, escitalopram, ethinylestradiol, felodipine, fentanyl, imatinib, lovastatin, midazolam, mirtazapine, nifedipine, ondansetron, sertraline, simvastatin, sirolimus, tacrolimus, verapamil, venlafaxine, voriconazole

of the OATP system results in altered systemic drug bioavailability. For example, inhibition of OATP in the GI tract results in decreased systemic absorption whereas inhibition in the liver and kidneys results in decreased metabolism and excretion. Agents affecting P-gp also have similar effects on OATP. Some OATP inhibitors include grapefruit juice, cyclosporine, and rifampin. HMG-CoA reductase inhibitors (statins) and ACE inhibitors are examples of OATP substrates [7].

Cytochrome P450 (CYP450) isoenzyme system

The CYP450 isoenzyme system is a family of heme-containing enzymes responsible for phase I (the oxidative phase) of drug, endogenous steroids, and toxin metabolism [1,2]. These enzymes are found in the liver, lungs, kidneys, intestines, and brain [1]. Many enzyme families have been identified in humans, but only seven of them (CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4/5) are responsible for drug metabolism [1,9]. Enzyme induction or inhibition changes the mechanism by which drugs undergo phase I metabolism. Drugs that induce CYP450 activity increase the production of enzymes or decrease their breakdown. This leads to increased drug clearance and decreased drug concentrations. In the case of prodrugs requiring metabolic activation, CYP450 induction leads to increased drug concentrations. The time of onset for enzyme induction is difficult to predict, but generally occurs within days to weeks following administration, and is usually determined by the inducing drug's half-life and rate of enzyme turnover. In contrast, enzyme inhibition results in decreased drug clearance and increased drug concentrations. CYP450 inhibition of prodrug activation results in decreased drug concentrations. Enzyme inhibition usually begins immediately upon the administration of the inhibitor, and the duration corresponds to its half-life.

The net balance of a drug interaction depends on the inhibitory and inducing potency of each agent and on the available routes of substrate elimination. For example, if a drug is a weak inhibitor, the risk of an interaction occurring is relatively low when a substrate of the same family is coadministered. Likewise, if a drug has multiple pathways for elimination, the risk of a major drug interaction is low when an inhibitor or inducer of only one enzyme family is given [10]. Additionally, like the P-gp-mediated pathway, the magnitude of the interaction is higher if both drugs are administered orally and if the substrate undergoes significant first-pass metabolism. Selected inducers, inhibitors, and substrates of the CYP450 system are listed in Table 98.1 [1,9,10].

Uridine 5′-diphosphate glucuronosyltransferase (UGT) enzyme system

Enzymes belonging to the UGT family play a major role in phase II or the conjugative phase of metabolism. They are responsible for 35% of all drugs metabolized by phase II enzymes. During this phase, drug metabolites are made more hydrophilic to facilitate excretion [10,11]. UGT enzymes are primarily found in the liver, but also exist in the GI tract, lungs, nasal epithelium, and kidneys [12]. As with the CYP450 system, modulation of these enzymes can change a drug's concentration and result in altered pharmacologic responses. Tacrolimus, cyclosporine (CSP), and fluconazole are examples of UGT inhibitors and rifampin, phenytoin, and phenobarbital represent potent UGT inducers [11]. Examples of UGT substrates include posaconazole and mycophenolate [11].

Azole antifungals

Fluconazole

Fluconazole is a substrate of CYP2C9 and CYP3A4. It is a potent inhibitor of CYP2C9 but only weakly inhibits CYP3A4, when compared with other azole antifungals such as ketoconazole, itraconazole, and voriconazole [13]. Concurrent administration of fluconazole with CSP, statins, or warfarin results in increased levels of these drugs and thus an increased risk of adverse effects such as renal dysfunction, myopathy, and bleeding [14]. Close monitoring of drug concentrations, use of alternative agents, and frequent dosage adjustments should be used to minimize the severity of these interactions with fluconazole. Administration of potent inducers of CYP2C9 or CYP3A4 with fluconazole can lead to decreased

Table 98.2 Selected drug interactions with fluconazole

Drug	Mechanism	Effect	Management
Benzodiazepines [13,14]	(–) CYP3A4	↑ Benzodiazepine conc.	Monitor for ↑ sedation. Adjust dose accordingly
Calcineurin inhibitors (see Tables 98.5 and 98.6)			
Dihydropyridine calcium channel blockers [13,14]	(–) CYP3A4	↑ Dihydropyridine conc.	Monitor blood pressure and pulse. Adjust dose accordingly
Ergot alkaloids [15]	(–) CYP3A4	↑ Ergot alkaloid conc.	Contraindicated
Ethinylestradiol/norethindrone [14]	(–) Estradiol metabolism	↑ Estradiol conc.	Monitor for toxicity
Fentanyl [16]	(–) CYP3A4	↑ Or prolonged opioid effects	Monitor for toxicity. Adjust dose accordingly
Losartan [13]	(–) CYP2C9	↓ Losartan efficacy	Monitor for efficacy
Phenytoin [13,14]	(–) CYP2C9	↑ Risk of phenytoin toxicity	Monitor phenytoin conc. and toxicity. Adjust dose accordingly
Rifabutin [13,14]	(–) CYP3A4	↑ Rifabutin conc. 80%	Avoid concomitant use. Monitor for toxicity
Rifampin [13,14]	(+) CYP3A4	↓ Fluconazole efficacy	Monitor for efficacy
Sirolimus (see Table 98.8)			
Sulfonylureas [13]	(–) CYP3A4	↑ Risk of hypoglycemia	Monitor blood glucose. Adjust dose accordingly
Warfarin [13,14]	(–) CYP2C9	↑ Prothrombin time 2-fold	Monitor prothrombin time. Adjust dose accordingly

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme; CYP2C9 = cytochrome P450 2C9 isoenzyme.

fluconazole serum levels and less effective antifungal therapy [13]. Selected drug interactions reported with fluconazole are described in Table 98.2 [13–16].

Itraconazole

Itraconazole is a substrate and potent inhibitor of CYP3A4. As a consequence, the interactions with it may be greatly enhanced compared with fluconazole. An example of this difference in magnitude of effect is seen when either azole is given with cyclosporine. Little or no change in CSP concentrations has been reported when fluconazole is given concurrently, but during coadministration with itraconazole, one study showed CSP levels to be elevated by a mean of 80%, necessitating dosage reductions [17]. Since the cost of CSP can be significant, this interaction has been viewed by some as beneficial and even prompted clinicians to use it as a cost-saving measure [18]. An important interaction between itraconazole and sirolimus is described later in this chapter.

Itraconazole is also a substrate and inhibitor of P-gp [19]. One of the interactions affected by this system involves digoxin. In a study of healthy subjects, itraconazole increased the digoxin area under the curve (AUC) by approximately 50% and decreased renal clearance by about 20% [20]. This is caused by itraconazole interfering with P-gp-mediated digoxin renal tubular secretion. Therefore, a 50% digoxin dose reduction is recommended when starting itraconazole. Digoxin concentrations and signs or symptoms of toxicity should be monitored. Other inhibitors of P-gp, like posaconazole, can increase the levels of digoxin when given together [19].

Cardiovascular drug effects can be enhanced via interactions with itraconazole. For instance, the AUC of felodipine increases sixfold and C_{max} eightfold, leading to rapid heart rate and low blood pressure [21]. Quinidine and dofetilide are contraindicated with itraconazole owing to the potential for QTc prolongation and torsades de pointes [22]. Through CYP2C9 inhibition, itraconazole can potentiate the anticoagulant effect of warfarin. In a case report, the international normalized ratio (INR) exceeded 8, which contributed to severe bruising and bleeding [23]. When used in conjunction with itraconazole, it is imperative to follow INRs closely and watch for signs of toxicity.

The efficacy of itraconazole is related to its serum concentration [17]. If its metabolism is induced by drugs such as phenytoin and rifampin, serum levels may be suboptimal, leading to inadequate control or progression of a fungal infection [24,25]. It may be useful to monitor itraconazole levels if such combinations are required, although some would advise against using them concomitantly since treatment failure may result.

Voriconazole

Voriconazole is also extensively metabolized by the CYP450 system and its inhibitory potency of CYP450 is between those of fluconazole and itraconazole. Specifically, voriconazole is a moderate inhibitor and substrate of CYP3A4, a moderate inhibitor but a weak substrate of CYP2C9, and a moderate inhibitor but strong substrate of CYP2C19. It is not an inhibitor or substrate of P-gp [11]. Since voriconazole affects multiple CYP pathways, it is reasonable to expect that the potential for drug–drug interactions is high.

Among the many drug interactions associated with voriconazole, its effects on cyclosporine, tacrolimus, and sirolimus are the most clinically relevant in HCT. Inhibition of CYP3A4-mediated metabolism of these immunosuppressants resulted in increases in AUC and blood concentrations in solid organ and HCT patients receiving concurrent voriconazole therapy [11]. More details regarding these interactions are provided in the respective immunosuppression sections and tables of this chapter. Close monitoring of immunosuppressive levels and dosage adjustments are imperative to avoid toxicity or therapeutic failures when voriconazole is being added or discontinued.

Voriconazole is contraindicated with pimozide, quinidine, and ergot alkaloids because of the concern for QTc prolongation and ergotism [26]. Increased incidence of voriconazole treatment failures is common when combined with potent inducers such as rifampin, rifabutin, and carbamazepine. Consequently, the use of these agents with voriconazole is also contraindicated [26].

Pharmacokinetic studies of voriconazole's effect on chemotherapy have been conducted with various agents [26]. Although voriconazole's theoretical interaction with cyclophosphamide has not been formally evaluated, it is of particular interest in HCT. Additional details of this interaction are described in the cyclophosphamide section.

Voriconazole concentrations are decreased by phenytoin and human immunodeficiency virus antivirals, whereas drugs such as cimetidine, erythromycin, and indinavir have negligible effects on its metabolism [27]. Voriconazole also decreases the metabolism of statins, phenytoin, and warfarin [28]. It has minor to negligible effects on prednisolone, digoxin, and mycophenolic acid derivatives. Table 98.3 further describes the clinically relevant drug interactions with voriconazole [1,27].

Table 98.3 Selected drug interactions with voriconazole

Drug	Mechanism	Effect	Management
Benzodiazepines [1]	(–) CYP3A4	↑ Benzodiazepine conc.	Monitor for ↑ sedation. Adjust dose accordingly
Calcineurin inhibitors (see Tables 98.5 and 98.6)			
Calcium channel blockers (diltiazem, verapamil) [26]	(–) CYP3A4	↑ Calcium channel blocker conc.	Monitor BP and HR. Adjust dose accordingly
Carbamazepine [26]	(+) CYP3A4	↓ Voriconazole conc.	Contraindicated
Ergot alkaloids [26]	(–) CYP3A4	↑ Ergot alkaloid conc.	Contraindicated
Ethinylestradiol/norethindrone [26]	(–) CYP2C19	↑ Voriconazole C_{max}, AUC ↑ Ethinylestradiol/ norethindrone C_{max}, AUC	Monitor for voriconazole toxicity and for menstrual bleeding
HMG-CoA reductase inhibitors (see Table 98.9)			
Macrolide (clarithromycin, erythromycin) [26]	(–) CYP3A4	↑ Macrolide conc.	Monitor EKG for QT_c prolongation. Consider alternative macrolide (e.g. azithromycin)
Methadone [26]	(–) CYP2C19, CYP2C9, CYP3A4	↑ Active (*R*)-methadone C_{max} 31%, AUC 47%	Monitor for toxicity. Adjust dose accordingly
Phenytoin [26]	(–) CYP2C9	↑ Phenytoin C_{max}, AUC 2-fold	Monitor phenytoin conc. and toxicity
	(+) CYP3A4	↓ Voriconazole C_{max} 50%, AUC 70%	↑ Voriconazole maintenance to 5 mg/kg IV BID (from 4 mg/kg) or to 400 mg PO BID (from 200 mg)
Proton pump inhibitors (PPIs) [26]	(–) CYP2C19, CYP2C9, CYP3A4	↑ PPI conc.	↓ Omeprazole 50% if dose >40 mg/day
Rifabutin [26]	(+) CYP3A4	↓ Voriconazole C_{max} 93%	Contraindicated
Rifampin [26]		↓ Voriconazole conc.	Contraindicated
Sirolimus (see Table 98.8)			
Sulfonylureas [26]	(–) CYP2C9	↑ Sulfonylurea conc.	Monitor blood glucose. Adjust dose accordingly
Warfarin [26]	(–) CYP2C9	↑ PT, INR	Monitor for bleeding, PT, INR. Adjust dose accordingly

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; AUC = area under the curve; C_{max} = maximum concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme; CYP2C19 = cytochrome P450 2C19 isoenzyme; CYP2C9 = cytochrome P450 2C9 isoenzyme; PT = prothrombin time; INR = international normalized ratio

Posaconazole

Like all azoles, posaconazole inhibits CYP3A4, and like fluconazole, it is not a substrate [11]. The primary metabolism of posaconazole is through glucuronidation by UGT enzymes. It is also a P-gp inhibitor and substrate like itraconazole. Posaconazole is contraindicated with pimozide and quinidine because of the potential for QTc prolongation and torsades de pointes [29]. Ergot alkaloids are contraindicated since they can precipitate ergotism [29]. Some drugs metabolized through CYP3A4, such as diltiazem and verapamil, have not been formally studied, but are likely to have an interaction with posaconazole [29]. Other benzodiazepines and statins listed in Table 98.4 may also have their concentrations elevated by concomitant posaconazole administration [29]. Inducers reduce posaconazole plasma levels and should be avoided unless the benefit exceeds the risk [30]. Relevant interactions occurring with posaconazole are summarized in Table 98.4 [19,29–32].

Similarly to itraconazole and voriconazole, posaconazole has inhibitory effects on the calcineurin inhibitors, requiring dosage adjustments and frequent monitoring of their levels. When the combination of posaconazole and CSP was analyzed in allogeneic transplant patients, the CSP levels increased, requiring about a 50% decrease in the dose [31]. Despite the makers of posaconazole recommending a cyclosporine dose reduction of 25% when posaconazole is added, this was not done preemptively in this study. The authors advised not to reduce the CSP dose empirically at the start of coadministration, but instead, to follow levels closely with subsequent adjustment since potential subtherapeutic levels may adversely affect the outcome of transplant, including increased rates of graft-versus-host disease (GVHD). The same might also be true for sirolimus. A description of this interaction can be found in the sirolimus section.

Echinocandins

In comparison with other antifungals, echinocandins are the least dependent on Pg-p, OATP, and CYP pathways for drug transport and metabolism. Micafungin in vitro was found to be a substrate and weak inhibitor of CYP; however, this was not demonstrated with in vivo studies [33]. Caspofungin is a substrate for OATP transport. Anidulafungin is not affected by these pathways [33,34]. Consequently, serious drug interactions with echinocandins are minimal.

The interaction between echinocandins and calcineurin inhibitors warrants some elaboration. In two studies, CSP inhibited OATP-mediated transport of caspofungin. This resulted in a 35% increase in the caspofungin AUC and transient elevations in transaminases [35,36]. However, subsequent retrospective reviews found negligible hepatotoxicity when this combination was employed [37,38]. Regardless, the manufacturer has cautioned against using these agents together unless the potential benefits outweigh the risks and, if used, monitoring of liver function tests is imperative. Conversely, tacrolimus concentrations, as described by AUC, maximum concentrations (C_{max}), and 12-hour blood levels decreased by 20, 16, and 26%, respectively [35,36]. Routine monitoring of tacrolimus concentrations with appropriate adjustments is advised. Micafungin mildly inhibited CSP metabolism in 20% of healthy volunteers; however, this was not observed in a study with HCT patients [39,40]. Careful monitoring for signs of CSP toxicity and adjustment of levels may be necessary when micafungin is initiated or discontinued. Anidulafungin concentrations were increased by 22% when given with CSP, but this interaction does not require any dosing modification [33]. Clinically significant interactions between tacrolimus and micafungin or anidulafungin have not been reported [33].

Other relevant echinocandin interactions include caspofungin with rifampin and micafungin with sirolimus and nifedipine. Concurrent administration of caspofungin and rifampin resulted in

Table 98.4 Selected drug interactions with posaconazole

Drug	Mechanism	Effect	Management
Calcineurin inhibitors			
Cyclosporine (CSP) [19,31]	(–) CYP3A4, P-gp	↑ CSP conc.	↓ CSP dose 25%. Monitor CSP conc. Adjust dose accordingly
Tacrolimus [19]		↑ Tacrolimus AUC 358%, C_{max} 121%	↓ tacrolimus dose 66%. Monitor tacrolimus conc. Adjust dose accordingly
Cimetidine [19]	Alteration of gastric pH	↓ Posaconazole AUC and C_{max} 39%	Avoid concomitant use
Digoxin [19,29]	(–) P-gp	↑ Digoxin conc.	Monitor digoxin conc.
Esomeprazole [19]	Alteration of gastric pH	↓ Posaconazole AUC 32%, C_{max} 46%	Avoid in lower absorption states (e.g. GVHD, mucositis)
Midazolam [19]	(–) CYP3A4	↑ Midazolam AUC up to 10-fold, C_{max} up to 3-fold	Monitor for toxicity
Phenytoin [19]	(–) CYP3A4 (+) UGT	↑ Phenytoin AUC and C_{max} 16% ↓ Posaconazole AUC 50%, C_{max} 41%	Avoid concomitant use. If used, monitor for therapeutic failure and phenytoin conc.
Rifabutin [19,30]	(–) CYP3A4 (+) UGT	↑ Rifabutin AUC 72%, C_{max} 31% ↓ Posaconazole AUC 49%, C_{max} 43%	Avoid concomitant use. If used, monitor for therapeutic failure and rifabutin toxicity
Rifampin [32]	(+) UGT	↓ Posaconazole conc. up to 80.3%	Avoid concomitant use. If used, monitor for therapeutic failure
Simvastatin (see Table 98.9)			
Sirolimus (see Table 98.8)			

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme, P-gp = P-glycoprotein; UGT = uridine 5′ diphosphate glucuronosyltransferase; AUC = area under the curve; C_{max} = maximum concentration.

Table 98.5 Selected drug interactions with cyclosporine (CSP)

Drug	Mechanism	Effect	Management
Azoles			
Fluconazole [42]	(–) CYP3A4	↑ CSP conc. 21%	Monitor CSP conc. Adjust dose accordingly
Itraconazole [17]		↑ CSP conc. 80%	↓ CSP dose ~50%. Monitor CSP conc. Adjust dose accordingly
Posaconazole [29]		↑ CSP conc.	↓ CSP dose 25%. Monitor CSP conc. Adjust dose accordingly
Voriconazole [43]		↑ CSP AUC 1.7-fold, conc. 2.5-fold	↓ CSP dose 50%. Monitor CSP conc. Adjust dose accordingly
Diltiazem [44]	(–) CYP3A4	↑ CSP AUC 28–62%, conc. 49–88%	Monitor CSP conc. Adjust dose accordingly
Carbamazepine [45]	(+) CYP3A4	↓ CSP conc. 50%	Monitor CSP conc. Adjust dose accordingly
Caspofungin [35]	(–) CYP3A4	↑ Caspofungin AUC 35%	Avoid concomitant use. Monitor liver function tests
Digoxin [46]	Unknown	↑ Digoxin conc., ↓ Cl 53%	Consider ↓ digoxin dose ~50%. Monitor digoxin conc.
HMG-CoA reductase inhibitors (see Table 98.9)			
Imatinib [47]	(–) CYP3A4	↑ CSP conc. 1.7-fold	Monitor CSP conc. Adjust dose accordingly
Metronidazole [48]	? (–) CYP3A4	↑ CSP conc. 2-fold	Monitor CSP conc. Adjust dose accordingly
Mycophenolic acid derivatives (see Table 98.7)			
Phenobarbital [49]	(+) CYP3A4	↓ CSP conc.	Monitor CSP conc. Adjust dose accordingly
Phenytoin [49]	(+) CYP3A4	↓ CSP conc.	Monitor CSP conc. Adjust dose accordingly
Rifampin [50]	(+) CYP3A4	↓ CSP AUC	Avoid concomitant use. Monitor CSP conc. Adjust dose accordingly
Sirolimus (see Table 98.9)			

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme; ALT AUC = area under the curve; Cl = clearance.

a transient 61% increase followed by a 14–30% reduction in caspofungin concentration at the steady state [33]. It is believed that this interaction is OATP mediated since both drugs are OATP substrates and rifampin has both inductive and inhibitory effects on OATP transport [33]. To avoid possible therapeutic failure, the daily caspofungin dose should be increased to 70 mg. This higher dose should also be considered when other known inducers are added to caspofungin [33]. Coadministration of micafungin with sirolimus and nifedipine resulted in 12 and 18% increases in sirolimus and nifedipine concentrations, respectively [33]. Dose adjustments of both agents may be necessary if given together with micafungin.

Immunosuppressants

Calcineurin inhibitors

The metabolisms of both CSP and tacrolimus are mediated predominantly through CYP3A4. They are CYP3A4 substrates and inhibitors and substrates of P-gp [41]. Therefore, they have similar drug interaction profiles. These are depicted in Table 98.5 [17,29,35,42–50] and Table 98.6 [17,29,35,42,51–58]. Differences may be attributed to the relative contributions of liver or intestinal metabolism, affinity to bind to specific CYP isoenzymes, and involvement of other transporter systems [41]. Also, published data may be lacking in some instances, but the potential for interaction may still exist, as in the case of imatinib with tacrolimus.

Knowing which agents may affect the concentrations of these medications is critical because the calcineurin inhibitors have a narrow therapeutic window. Too much of either drug results in toxicity (nephrotoxicity, neurotoxicity, etc.), whereas too little will cause inadequate immunosuppression and possibly lead to increased risk of GVHD or graft rejection.

In a study of calcineurin inhibitors and voriconazole in allogeneic HCT patients, the median increase in tacrolimus concentration to dose (C/D) ratio was 115.6% [59]. In those who received CSP, the C/D ratio was 82.1%, suggesting a smaller interaction. Considerable interpatient variability was observed in the magnitude of the

Table 98.6 Selected drug interactions with tacrolimus

Drug	Mechanism	Effect	Management
Azoles			
Fluconazole [42]	(–) CYP3A4	↑ Tacrolimus conc. 16%	Monitor tacrolimus conc. Adjust dose accordingly
Itraconazole [17]		↑ Tacrolimus conc. 83%	↓ Tacrolimus dose ~50%. Monitor tacrolimus conc. Adjust dose accordingly
Posaconazole [29]		↑ Tacrolimus AUC 358%, C_{max} 121%	↓ Tacrolimus dose 66%. Monitor tacrolimus conc. Adjust dose accordingly
Voriconazole [51]		↑ Tacrolimus conc. 10-fold	↓ Tacrolimus dose 66%. Monitor tacrolimus conc. Adjust dose accordingly
Calcium channel blockers			
Diltiazem [52]	(–) CYP3A4	↑ Tacrolimus conc.	Monitor tacrolimus conc. Adjust dose accordingly
Felodipine [53]		↑ Tacrolimus conc. 3-fold	
Caspofungin [35]	Unknown	↓ Tacrolimus AUC 20%, C_{max} 16%, conc. 26%	Monitor tacrolimus conc. Adjust dose accordingly
Clarithromycin [54]	(–) CYP3A4	↑ Tacrolimus conc.	Monitor tacrolimus conc. Adjust dose accordingly
Metronidazole [55]	? (–) CYP3A4, P-gp	↑ Tacrolimus conc. 3-fold	Monitor tacrolimus conc. Adjust dose accordingly
Phenobarbital [56]	(+) CYP3A4	↓ Tacrolimus conc. 73%	Monitor tacrolimus conc. Monitor for ↑ risk of GVHD. Adjust dose accordingly
Phenytoin [57]	(+) CYP3A4	↓ Tacrolimus conc.	Monitor tacrolimus conc. Monitor for ↑ risk of GVHD. Adjust dose accordingly
Rifampin [58]	(+) CYP3A4	↓ Tacrolimus conc., requiring 10-fold ↑ in tacrolimus dose	Avoid concomitant use
Sirolimus (see Table 98.8)			

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme; AUC = area under the curve; C_{max} = maximum concentration; P-gp = P-glycoprotein.

interaction, leading the authors to recommend not uniformly reducing the dose of calcineurin inhibitors. In another trial examining the concomitant use of tacrolimus and voriconazole in transplant recipients, a preemptive dose reduction strategy was utilized to maintain tacrolimus levels successfully within the targeted goal [60]. Doses were lowered by 60–80% compared with those at baseline. Although the manufacturer's recommendations suggest preemptively decreasing the immunosuppressant doses when azoles are initiated, these came from limited data in renal transplant recipients and healthy volunteers [26]. In clinical practice, some may choose to adhere to the prescribing guidelines or opt to monitor drug concentration closely s and adjust doses as needed.

When orally administered tacrolimus and voriconazole were evaluated in HCT patients, the median increase in the C/D ratio of tacrolimus was 138.8% [61]. Since CYP3A4 enzymes are found in the liver and GI tract, the interaction is greater than when both drugs are given intravenously. Additionally, if the immunosuppressant is a substrate of P-gp and an azole is a P-gp inhibitor, then the bioavailability of the immunosuppressant is further enhanced. Therefore, when changing from intravenous to oral dosing, a dosage reduction may be required [41].

Proton pump inhibitors (PPIs) are metabolized mainly via CYP2C19 and CYP3A4, hence drug interactions with calcineurin inhibitors would be expected. The data, however, are conflicting with both tacrolimus and cyclosporine. In a case report involving a kidney transplant recipient, the tacrolimus concentration was increased to over 20 ng/mL when esomeprazole and omeprazole were used at different times [62]. In contrast, the interaction between omeprazole and tacrolimus was deemed a clinically irrelevant drug interaction in 51 renal allograft patients [63]. Lansoprazole, however, was shown to interact with tacrolimus in several case reports [64,65]. This was particularly evident in those who had CYP2C19 gene mutations and were intermediate or poor metabolizers, which shifted the metabolism of lansoprazole to the 3A4 pathway and, consequently, a greater increase in tacrolimus AUC [66]. Pantoprazole and rabeprazole have not been shown to interact with tacrolimus. Studies and case reports have shown either an insignificant interaction, or both increases and decreases in cyclosporine levels when used concomitantly with PPIs [67]. The package labeling on omeprazole cautions that it may prolong cyclosporine's elimination. A theoretical interaction with rabeprazole also exists. In vitro, it has been shown to inhibit cyclosporine metabolism similarly to omeprazole at equivalent concentrations, but no in vivo clinical reports have been published. Nonetheless, close monitoring and dosage adjustments may be warranted when PPIs are used concurrently with calcineurin inhibitors. Two specific drugs that alter the metabolism of CSP and tacrolimus in different ways are caspofungin and sirolimus. These interactions are further characterized in their respective sections. The cyclosporine–posaconazole interaction is also illustrated in the posaconazole section.

Mycophenolic acid (MPA) derivatives

The metabolism of mycophenolate mofetil (MMF) and mycophenolic sodium is complex; it involves the rapid conversion to mycophenolic acid (MPA), metabolism of MPA to 7-*O*-MPA glucuronide (MPAG) by UGT enzymes, possible MPAG enterohepatic recirculation by intestinal bacteria, and MPAG excretion by active tubular secretion and, to a lesser extent, Pg-p, into the urine [68].

Decreased absorption, inhibition of enterohepatic recycling, and competition for renal tubular secretion are the main mechanisms by which drug interactions occur with these agents. Reductions in MPA exposure can lead to therapeutic failures, whereas increases can result in toxicities such as hypersensitivity, GI disturbances, and cytokine release [68]. Drugs interacting with MPA derivatives and their clinical implications are discussed below and presented in Table 98.7 [68–73].

Coadministration of agents such as oral divalent electrolyte supplements and phosphate binders have been shown to reduce absorption, leading to lower concentrations of MPA [68,69,73]. Reduction in MPA C_{max} and AUC of orally administered MMF, but not mycophenolic sodium, was observed with concurrent

Table 98.7 Selected drug interactions with mycophenolic acid derivatives

Drug	Mechanism	Effect	Management
Antacids [68]	↓ MPA absorption	↓ MPA absorption	Monitor for therapeutic failure
Bile acid binders [68]	(–) Enterohepatic recycling	↓ MPA AUC 40%	Avoid concomitant use
Cyclosporine [69]	(–) Enterohepatic recycling	↓ MPA conc.	Monitor for therapeutic failure
Divalent oral electrolyte supplement [70]	↓ MMF absorption via chelation	↓ MPA absorption	Monitor for therapeutic failure
Ganciclovir [70]	Competes for renal tubular secretion	↑ Ganciclovir conc. in renal impairment	Monitor blood counts
Oral contraceptives [70]	Unknown	↓ Oral contraceptive exposure	Monitor for menstrual bleeding
Proton pump inhibitors [61]	↓ MMF dissolution and MPA conversion	↓ MPA absorption	Use mycophenolic sodium
Rifampin [72]	(+) UGT, (–) enterohepatic recycling	↓ MPA AUC	Monitor for therapeutic failure
Sevelamer [73]	↓ MMF absorption, (–) enterohepatic recycling	↓ MPA AUC 25%, C_{max} 30%	Separate by ≥2 hours

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; conc. = concentration; C_{max} = maximum concentration; AUC = area under the curve; MMF = mycophenolate mofetil; MPA = mycophenolic acid; UGT = uridine 5′-diphosphate glucuronosyltransferase.

Table 98.8 Selected drug interactions with sirolimus

Drug	Mechanism	Effect	Management
Azoles [41]			
Fluconazole	(–) CYP3A4, P-gp	↑ Sirolimus conc. 3-fold	Monitor sirolimus conc. Monitor for toxicity.
Itraconazole		↑ Sirolimus conc. > 8-fold	Adjust dose accordingly. See text
Posaconazole		↑ Sirolimus AUC 8.9-fold, C_{max} 6.7-fold	Contraindicated. See text
Voriconazole		↑ Sirolimus AUC 7-fold, C_{max} 11-fold	
Calcium channel blockers [76]			
Diltiazem	(–) CYP3A4, P-gp	↑ Sirolimus C_{max} 1.4-fold, t_{max} 1.3-fold, AUC 1.6-fold	Monitor sirolimus conc. Monitor for toxicity. Adjust dose accordingly
Verapamil		↑ Sirolimus C_{max} 2.3-fold, AUC 2.2-fold ↓ Active (*S*)-(–)-enantiomer of verapamil C_{max}, AUC 1.5-fold	
Calcineurin inhibitors			
CSP [78]	(–) CYP3A4, P-gp	↑ Sirolimus C_{max} 116%, AUC 230%.	Administer sirolimus 4 hours after CSP
Tacrolimus [79]		↓ Tacrolimus conc.	Monitor tacrolimus conc.
Erythromycin [76]	(–) CYP3A4, P-gp	↑ Sirolimus C_{max} 4.4-fold, AUC 4.2-fold, t_{max} 0.4 h ↑ Erythromycin C_{max} 1.6-fold, AUC 1.7-fold, t_{max} 0.3 h	Monitor sirolimus conc. Monitor for toxicity. Adjust dose accordingly
Micafungin [76]	Unknown	↑ Sirolimus AUC 21%	Monitor sirolimus conc. Monitor for toxicity. Adjust dose accordingly
Rifampin [76]	(+) CYP3A4, P-gp	↓ Sirolimus AUC 82%, C_{max} 71%	Monitor sirolimus conc. Monitor for toxicity. Adjust dose accordingly or use alternative agent

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; C_{max} = maximum concentration; t_{max} = time to maximum concentration; AUC = area under the curve; CYP3A4 = cytochrome P450 3A4 isoenzyme; P-gp = P-glycoprotein.

treatment with PPIs. This difference is due in part to the dependence of an acidic environment for MMF dissolution and conversion to MPA, and consequently MPA absorption in the stomach. In contrast, dissolution of mycophenolic sodium to MPA is not acidic pH dependent [71].

CSP but not sirolimus or tacrolimus administration was shown to decrease MPA concentrations through P-gp inhibition and consequently enterohepatic recycling of MMF [69,74,75]. Other inhibitors of enterohepatic recycling include bile acid sequestrants, rifampin, and to some extent sevelamer [69,72,73].

Competition for renal excretion of MPA is also a possible mechanism for drug interactions. Ganciclovir is an example of a drug that interacts via this mechanism [70].

Sirolimus

Sirolimus is a substrate and inhibitor of P-gp and CYP3A4 [76,77]. Consequently, concomitant administration of sirolimus with inducers of CYP3A4 and P-gp leads to increased sirolimus metabolism, decreased concentration, decreased efficacy, and potentially increased GVHD. Likewise, the converse is true when sirolimus is given with CYP3A4 or P-gp inhibitors. Monitoring sirolimus trough levels and signs of toxicity and treatment failure is recommended when combined with agents mediated by CYP3A4 or P-gp. Sirolimus interactions with azole antifungals and calcineurin inhibitors are discussed below. Additional interactions are presented in Table 98.8 [41,76,78,79].

Decreased sirolimus metabolism and supratherapeutic levels are well documented with the azole antifungals. Empiric dosage reduction of ketoconazole (by 80–90%) and daily doses of fluconazole ≥200 mg (by 50–70%) are recommended to mitigate the magnitude of the interaction. Caution should be exercised , however, when reducing the doses of these agents since interpatient variability can widely affect the incidence, magnitude, and significance of the interaction [41]. The interaction of sirolimus with itraconazole exists in case reports. In two solid organ transplant reports, an 8.5-fold increase in sirolimus levels was reported when itraconazole was added and a twofold increase in sirolimus dose was necessary to maintain similar immunosuppressant levels when itraconazole was discontinued [80]. Similarly, in an HCT setting, a doubling of sirolimus concentration was noted following 1 week of concurrent therapy when added to itraconazole. This resulted in the need to withhold sirolimus for 8 days followed by a 3.5-fold sirolimus dosage reduction. The authors of this report recommended caution when adding either agent to or removing it from existing sirolimus or itraconazole therapy. In addition, sirolimus concentration monitoring and judicious use of sirolimus dose adjustments were suggested [80]. Voriconazole labeling contraindicates its use with sirolimus due to a sevenfold increase in C_{max} and an 11-fold increase in the AUC of sirolimus [76]. Case reports, however, have described the safe administration of this combination [81]. Mathis et al. cited a 75–87% dosage reduction in sirolimus during therapy with voriconazole in two renal transplant patients [81]. Similarly, Marty et al. reported the use of sirolimus and voriconazole in 11 patients undergoing HCT [82]. In this case series, the sirolimus dose was empirically reduced by 90% upon initiation of voriconazole. The investigators of both studies concluded that the combination is feasible and safe. Frequent monitoring of sirolimus levels upon initiation and discontinuation of voriconazole was also recommended. Posaconazole increased sirolimus exposure 6.7-fold in C_{max} and 8.9-fold in AUC when given together. The authors of this study and posaconazole labeling contraindicate the concomitant use of these agents [11,83]. Evaluation in 15 HCT patients, however, showed that this combination is feasible in the setting of an empiric 33–50% sirolimus dose reduction [77]. In general, close monitoring of sirolimus levels and adjustments in dosage are recommended to optimize therapy during and upon the discontinuation of azole use.

Systemic sirolimus exposure in healthy volunteers is affected by the timing of sirolimus administration in relation to CSP through CSP-mediated inhibition of P-gp and CYP3A4. Statistically significant increases in the bioavailability, C_{min}, C_{max}, time to C_{max}, and AUC of sirolimus were observed when both agents were taken together. In contrast, when sirolimus was administered 4 hours after CSP, these measures were modestly increased. The pharmacokinetics of CSP were unaffected by sirolimus. The authors advised that sirolimus should be administered 4 hours after CSP to avoid toxic sirolimus levels [78]. Changes in sirolimus pharmacokinetics were not demonstrated with tacrolimus. However, a reduction in tacrolimus levels occurred with this combination compared with tacrolimus alone [79].

Chemotherapy

Busulfan

Busulfan has a narrow therapeutic window and, as a result, interactions involving this drug are noteworthy. It is primarily metabolized via glutathione conjugation, and subsequently oxidative transformation in the liver [84]. Acetaminophen depletes glutathione, which in turn reduces busulfan clearance. Hence it should not be administered concomitantly with or within 72 hours of busulfan [84]. Itraconazole, but not fluconazole, reduced the clearance of busulfan by 20%, resulting in elevated busulfan levels [85]. Theoretically, voriconazole could interact with busulfan by decreasing its clearance through inhibition of glutathione conjugation [86]. Therefore, the combination of itraconazole and voriconazole with busulfan should be avoided. Currently, interaction data regarding posaconazole and busulfan have not been reported.

Metronidazole increases busulfan levels, thus contributing to severe toxicity and even mortality [87]. Although the exact mechanism is unclear, it is possible that metronidazole inhibits CYP3A4-mediated metabolism of busulfan. Metronidazole and busulfan should not be used concurrently.

Phenytoin reduces busulfan concentrations by inducing its metabolism [84]. In one study, a decline of 15% or more in busulfan levels was noted in the phenytoin group versus subjects who received diazepam for seizure prophylaxis [88]. Based on these findings, the use of alternative anticonvulsants has been promoted. Options such as benzodiazepines and levetiracetam may be considered. If continued use of phenytoin is desired, the interaction can be managed by adjusting busulfan doses based on busulfan pharmacokinetics. Of the other antiepileptics, levetiracetam may be preferred to benzodiazepines given its favorable pharmacokinetic profile such as a short half-life, excellent bioavailability, and low potential for drug interactions [89,90]. Cyclophosphamide may also interact with phenytoin, but the extent of the interaction is unpredictable given the complexity of cyclophosphamide's metabolism and the relatively short duration of phenytoin use in busulfan/cyclophosphamide conditioning regimens. Phenytoin has been employed as busulfan-induced prophylaxis for over 20 years [89]. In addition, head-to-head studies comparing phenytoin with alternative antiseizure agents looking at long-term outcomes are absent. Furthermore, the outcome data in HCT have historically been based on the use of phenytoin as seizure prophylaxis. Therefore, for these reasons, many transplant centers have not opted to change their prophylactic strategy.

Cyclophosphamide

When itraconazole was given as prophylaxis to HCT patients conditioned with cyclophosphamide, higher serum creatinine and bilirubin levels were seen in the subset who received itraconazole as opposed to fluconazole [91]. Those who were assigned to itraconazole had greater exposure to toxic metabolites linked to hepatic venocclusive disease (VOD). Fluconazole, however, showed a protective benefit by inhibiting the formation of a harmful metabolite, 4-hydroxycyclophosphamide (4-HC). Inhibition of CYP3A4 and CYP2C9 by voriconazole could potentially lead to altered cyclophosphamide activation, thereby reducing cyclophosphamide's efficacy or producing undesirable toxicity analogous to that of itraconazole. Alternatives to voriconazole, such as echinocandins or amphotericin-based products, should be employed to avoid the potential interaction. If temporary cessation of voriconazole is possible, it should be discontinued at least 30 hours prior to starting cyclophosphamide and resumed when five cyclophosphamide half-lives have elapsed [1].

The use of aprepitant, a neurokinin antagonist antiemetic with moderate CYP3A4 inhibitor activity, could potentially interact with high-dose cyclophosphamide used in conditioning; however, a study has shown no meaningful influence on cyclophosphamide pharmacokinetics [92].

An interaction between cyclophosphamide and cyclosporine has also been considered. In a review of allogeneic HCT patients, factors affecting cyclosporine concentrations up to 14 days after transplantation were elucidated [93]. It was found that cyclosporine levels were much lower in the group who received cyclophosphamide-based conditioning, as opposed to the others who did not. They postulated that cyclophosphamide autoinduction caused an increase in hepatic enzymes, leading to a decline in cyclosporine concentrations. Therefore, levels of the calcineurin inhibitor should be closely monitored, especially early after transplant and when cyclophosphamide is part of post-transplant GVHD prophylaxis.

Tyrosine kinase inhibitors (TKIs)

Imatinib is a P-gp, OATP, organic cation-transporting polypeptide (OCTP), and CYP3A4 and, to a lesser extent, CYP2C9 and CYP2D6 substrate [94,95]. It is also a potent inhibitor of these pathways [96]. Dasatinib is a CYP3A4 and P-gp substrate and a weak CYP3A4 inhibitor [94,97]. Nilotinib is a CYP3A4 and P-gp substrate but also competitively inhibits CYP3A4, CYP2C8, CYP2C9, CYP2D6, P-gp, and OCTP [94,95]. In contrast, sorafenib is excreted 95% unchanged. The remainder undergoes hepatic metabolism, where it is metabolized by CYP3A4 followed by glucuronidation by UGT1A9 [94]. It has been found to inhibit CYP2B6, CYP2C8, CYP2C9, CYP2D6, P-gp, and UGT1A1 in in vitro studies [96].

Table 98.9 Selected drug interactions with HMG-CoA reductase inhibitors

Drug	Interacting drug	Mechanism	Effect	Management
Lovastatin, simvastatin, atorvastatin [99,100]	Amiodarone	(–) CYP3A4	↑ Simvastatin, lovastatin, atorvastatin conc.	Simvastatin NTE 10 mg/day Lovastatin NTE 40 mg/day
	Amlodipine			Simvastatin NTE 20 mg/day
	Carbamazepine	(+) CYP3A4	↓ Simvastatin, lovastatin AUC 70–95-fold ↓ Atorvastatin AUC 60–90-fold	Monitor for therapeutic failure
	Clarithromycin	(–) CYP3A4	↑ Simvastatin, lovastatin AUC 4–12-fold ↑ Atorvastatin AUC 1.5–5-fold	Contraindicated with lovastatin, simvastatin
	Cyclosporine		↑ Simvastatin AUC 6–8-fold ↑ Lovastatin AUC 5–20-fold ↑ Atorvastatin AUC 6–15-fold	Contraindicated with simvastatin. Avoid with lovastatin
	Diltiazem		↑ Simvastatin, lovastatin AUC 3–8-fold	Simvastatin NTE 10 mg/day Lovastatin NTE 20 mg/day
	Gemfibrozil	(–) OATP1B1	↑ Simvastatin and lovastatin AUC 2–3-fold ↑ Atorvastatin AUC <1.5-fold	Contraindicated with simvastatin. Avoid with lovastatin
	Itraconazole	(–) CYP3A4	↑ Simvastatin, lovastatin AUC 5–10-fold ↑ Atorvastatin AUC 2–4-fold	Contraindicated with lovastatin, simvastatin
	Phenytoin	(+) CYP3A4	↓ Simvastatin, lovastatin, atorvastatin conc.	
	Posaconazole	(–) CYP3A4	↑ Simvastatin AUC 5–11-fold	Contraindicated with lovastatin, simvastatin
	Rifampin	(+) CYP3A4	↓ Simvastatin and lovastatin AUC 70–95-fold ↓ Atorvastatin AUC 60–90-fold	
	Verapamil	(–) CYP3A4	↑ Simvastatin, lovastatin, atorvastatin conc.	Simvastatin NTE 10 mg/day Lovastatin NTE 40 mg/day
	Warfarin	(–) Warfarin metabolism	↑ INR	Monitor for bleeding. Adjust dose accordingly
Fluvastatin [100,101]	Amiodarone Cyclosporine Fluconazole	(–) CYP2C9	↑ Fluvastatin conc. ↑ Cyclosporine AUC 2–4-fold	Monitor for toxicity
	Phenytoin Voriconazole	(+) CYP2C9	↓ Fluvastatin conc.	
	Warfarin	(–) Warfarin metabolism	↑ INR	Monitor for bleeding. Adjust dose accordingly
Pitavastatin [100]	Cyclosporine Gemfibrozil	(–) OATP1B1	↑ Pitavastatin AUC 5-fold ↑ Pitavastatin AUC <1.5-fold	Monitor for toxicity
Pravastatin [100,101]	Clarithromycin Cyclosporine Gemfibrozil	(–) OATP1B1	↑ Pravastatin AUC 2-fold ↑ Pravastatin AUC 5–10-fold ↑ Pravastatin AUC 2-fold	Monitor for toxicity
	Warfarin	(–) Warfarin metabolism	↑ INR	Monitor for bleeding. Adjust dose accordingly
Rosuvastatin [103]	Antacids	(–) Absorption	↓ Rosuvastatin conc. 50%	Administer 2 hours after rosuvastatin
	Cyclosporine	(–) CYP2C9, CYP2C19 (–) OATP1B1	↑ Rosuvastatin AUC 7.1-fold, C_{max} 10.6-fold	Monitor for toxicity
	Fluconazole	(–) CYP2C9, CYP2C19	↑ Rosuvastatin AUC, C_{max}	
	Gemfibrozil	(–) OATP1B1, UGT	↑ Rosuvastatin AUC 2-fold	
	Ursodiol	(–) OATP1B1, hepatic nuclear factor 1-alpha	↑ Rosuvastatin AUC	
	Warfarin	(–) CYP2C9 warfarin metabolism and displaces warfarin from protein-binding sites	↑ INR	Monitor for bleeding. Adjust dose accordingly

(–) = Inhibits; (+) = induces; ↑ = increases; ↓ = decreases; C_{max} = maximum concentration; conc. = concentration; CYP3A4 = cytochrome P450 3A4 isoenzyme; OATP1B1 = organic anion transport peptide 1B1; UGT = uridine 5′-diphosphate glucuronosyltransferase; CYP2C9 = cytochrome P450 2C9 isoenzyme; CYP2C19 = cytochrome P450 2C19 isoenzyme; AUC = area under the curve; INR = international normalized ratio; NTE = not to exceed.

The use of imatinib with P-gp inhibitors, such as pantoprazole, results in increased imatinib systemic exposure [96]. A 70% reduction in imatinib plasma levels was observed when potent CYP3A4 inducers were coadministered. Consequently, imatinib doses of 600–700 mg daily may be needed in the setting of concurrent therapy with CYP inducers. Conversely, concomitant administration of ketoconazole and imatinib resulted in a 40% increase in the AUC and a 26% increase in C_{max} of imatinib[96]. As a result, an imatinib dose of 300 mg daily is recommended with ketoconazole. Caution is advised when using imatinib with other known CYP3A4 inhibitors [96]. Imatinib was shown to increase CSP concentrations 1.7-fold through inhibition of CYP3A4 [47]. Administration of imatinib with other CYP3A4, CYP2D6, and CYP2C9 substrates should also be prescribed with caution [96]. Examples of these substrates include simvastatin, metoprolol, and warfarin, respectively. Avoidance or use of alternative therapies such as pravastatin, atenolol, and low molecular weight heparin, which do not utilize similar metabolic pathways to imatinib, are suggested. Dosage reductions of the substrate may be necessary if the interaction with imatinib is unavoidable.

The AUC and C_{max} of dasatinib are reduced by 60% when it is given concomitantly with antacids and H_2 blockers, and 40% when given with proton pump inhibitors [97,98]. This interaction can be managed by administering the antacid 2 hours before or after dasatinib [97]. Coadministration of dasatinib with CYP3A4 inhibitors may lead to an increase in dasatinib concentration and increased toxicity. Conversely, coadministration of dasatinib with CYP3A4 inducers could lead to a >80% reduction in dasatinib exposure and diminished efficacy [97].

The use of nilotinib with CYP3A4 inhibitors such as azole antifungals is not recommended owing to a 30% to threefold increase in nilotinib concentrations. If concurrent therapy is necessary, the dose of nilotinib should be reduced to 400 mg daily with close monitoring of the QTc interval [95]. Decreased nilotinib levels have occurred with concurrent use of CYP3A4 inducers. Nilotinib dose adjustments should be considered in these patients. Administration of P-gp inhibitors with nilotinib will also increase nilotinib exposure [95].

Like other TKIs, the use of sorafenib with rifampin resulted in 37% lower sorafenib concentrations [96]. Sorafenib doses up to 1000 mg daily are recommended when prescribed with rifampin [96]. A reduction in sorafenib concentration can be expected if it is coadministered with other CYP3A4 inducers. Interestingly, administration of sorafenib with ketoconazole, a CYP3A4 inhibitor, or warfarin, a CYP2C9 substrate, did not result in any alteration of sorafenib levels or coagulation parameters, respectively [96]. Inducers of UGT1A9 such as omeprazole have the potential to decrease the sorafenib AUC [94].

Statins

Atorvastatin, lovastatin, and simvastatin are CYP3A4 substrates whereas fluvastatin is a CYP2C9 substrate [11,99,100]. Atorvastatin, lovastatin, simvastatin, and pitavastatin are P-gp substrates and inhibitors whereas fluvastatin, rosuvastatin, and pravastatin are not [99,100]. All currently available statins are substrates of OATP1B1-mediated transport [99,100]. Administration of statins with drugs that are substrates, inhibitors, or inducers of CYP3A4, CYP2C9, P-gp, and OATP pathways may result in drug interactions. Selected interactions with statins are also described in Table 98.9.

The risk of myopathy or rhabdomyolysis is increased when azole antifungals are administered concurrently with statins. Inhibitors of CYP3A4 cause inhibition of statin metabolism, as evidenced by an increase in atorvastatin, lovastatin, and simvastatin concentrations [11]. In addition, concomitant use of itraconazole significantly increased the AUC of statins except fluvastatin. New package labeling contraindicates the use of lovastatin and simvastatin with itraconazole and posaconazole. [11,99,101]. The effect on the pravastatin AUC with itraconazole is conflicting [99]. In the case of the posaconazole–simvastatin interaction, posaconazole significantly increased the C_{max} and AUC of simvastatin (5–11-fold increase in AUC) [102]. The statin dose reduction should be considered when voriconazole is also prescribed. Fluconazole, a strong inhibitor of CYP2C9 and CYP2C19, causes clinically relevant increases in the AUC and C_{max} of rosuvastatin [103]. The use of statins that do not rely on CYP3A4 for metabolism or an empiric reduction in statin therapy with follow-up monitoring for efficacy are viable approaches to minimizing the risk of azole and statin drug interactions.

Cyclosporine is an inhibitor of P-gp, OATP, and CYP3A4. Inhibition of P-gp and CYP3A4 resulted in an increased AUC when CSP was combined with lovastatin, simvastatin, and atorvastatin [99]. A 20-fold increase in pravastatin and increases in rosuvastatin AUCs with cyclosporine therapy have also been reported. Inhibition of OATP2- and OATP1B1-mediated uptake by cyclosporine was implicated in these interactions [99,103]. A 3.1-fold increase in fluvastatin AUC was also noted with cyclosporine [99]. Vigilant monitoring for statin-related adverse effects, especially myopathy and rhabdomyolysis, is important. Limiting the statin dose or an empiric dose reduction may also be necessary in the setting of cyclosporine and pravastatin, rosuvastatin, or fluvastatin coadministration.

Therapeutic drug monitoring (TDM)

TDM is typically performed on drugs with a narrow therapeutic window, large pharmacokinetic variability, and/or when a direct relationship between plasma concentrations and clinical efficacy and toxicity exists [104]. TDM has historically been used as one method to monitor patient compliance with therapy, efficacy, and toxicity. It may also be useful for managing drug–drug interactions to achieve targeted blood concentrations. TDM is a well-established approach to individualized drug dosing for busulfan, posaconazole, voriconazole, cyclosporine, tacrolimus, and sirolimus. Assays for monitoring trough blood levels of these antifungals and immunosuppressants are available at most transplant centers and routinely used to monitor for therapeutic efficacy and toxicity. AUC monitoring following oral and intravenous busulfan administration is applied as standard in most transplant centers to target blood levels known to affect transplant outcomes, such as cure rates and limit toxicity such as VOD. TDM for cyclophosphamide, mycophenolic acid derivatives, and TKIs have been utilized in various research studies; however, the routine use of these assays in clinical practice is limited owing to the lack of assay availability and unknown clinical significance.

Conclusion

As new drugs are being developed and used in different combinations, the risk for drug interactions will always be a concern. Having a firm understanding of the mechanisms by which drugs are metabolized and eliminated is a powerful tool to help predict and possibly minimize the occurrence of these interactions in the HCT setting.

CHAPTER 99

Nutrition Support of the Hematopoietic Cell Transplant Recipient

Paula Charuhas Macris and Kerry K. McMillen
Seattle Cancer Care Alliance, Seattle, WA, USA

Introduction

Patients undergoing hematopoietic cell transplantation (HCT) are a highly heterogeneous population in terms of their nutrient needs and requirement for nutrition intervention. The implications of dose-intensive conditioning regimens, coupled with the debilitating effects of graft-versus-host disease (GVHD), can be extremely complex and adversely affect the patient's nutritional status. Decreased oral intake, increased nutrient requirements, and impaired nutrient utilization often necessitate medical nutrition therapy. The use of standard supportive care measures, including parenteral nutrition (PN), enteral nutrition (EN), and other dietary intervention strategies, such as the immunosuppressed diet, have varied over the past four decades and are highly dependent upon the type of transplant being utilized. This chapter highlights nutrition assessment components, appropriate nutrition support practices, and long-term management of nutritional sequelae associated with HCT.

Nutrition assessment

Initial and serial assessment is necessary for all patients undergoing HCT, owing to the anticipated nutrition issues associated with the conditioning regimen and other treatment-related toxicities that alter nutrient intake, absorption, and utilization [1]. A comprehensive evaluation is the foundation that identifies high-risk patients who may require aggressive nutrition intervention [2]. Frequent, ongoing nutrition assessment allows for a rapid response to sudden changes in clinical status.

Pre-transplant assessment

The baseline nutrition assessment may include data obtained from a patient-generated questionnaire, combined with further discussion with the patient and caregiver, and also the medical record, which elicits information about diet, use of nutritional supplements, prior need for nutrition support, subjective information on oral and gastrointestinal (GI) symptoms, and weight history. Components of the nutrition assessment are outlined below [2,3].

Nutrition history

- Oral/GI symptoms, including dysgeusia or hypogeusia, xerostomia, dysphagia or odynophagia, dental health, oral aversions, mucositis or esophagitis, heartburn or reflux, nausea and vomiting, early satiety, anorexia, altered bowel habits;
- current dietary modifications and special diets;
- food allergies or intolerances;
- use and dosage of vitamin, mineral, and herbal supplements;
- integrative medicine therapies;
- current or past nutrition support interventions (i.e. PN, EN) or intravenous fluid (IVF) support;
- infants and young children: if breast-fed, the mother's cytomegalovirus serology must be negative to prevent transmission of virus to the infant (Seattle Cancer Care Alliance, Standard Practice Guideline); if formula-fed, determine infant formula and concentration; assess stage of eating development (e.g., cup versus bottle; purée versus solid foods).

Anthropometry

- Accurate measurement of height and weight, which provide landmark data for serial measurements; for pediatric patients up to 24 months, a recumbent length and occipital frontal circumference are obtained and plotted on the Centers for Disease Control and Prevention growth charts;
- weight history and determination of ideal weight; for patients >120% ideal weight, an adjusted weight should be used; an example of a formula to calculate ideal weight is as follows [4]:

$$\text{adjusted weight} = (\text{actual weight} - \text{ideal weight}) \times 0.25 + \text{ideal weight};$$

- arm anthropometry, as an indicator of somatic muscle protein and adipose reserves, is most useful when obtained sequentially and compared over time [5].

Biochemical indices

- Baseline electrolytes, glucose, renal parameters, liver function enzymes, serum proteins, blood lipids, iron status, and 25-hydroxyvitamin D;
- information from baseline laboratory values serves as a guide to decisions about changes in nutrient and fluid requirements over time, especially if organ function changes [6].

Other assessment tools

- Medical history, including past surgeries and endocrine or cardiac complications;
- physical strength, exercise history, and activity level;

- organ function, noting any pre-existing alterations in renal or hepatic function;
- drug–nutrient interactions;
- visual assessment, noting presence of obesity, fluid retention, dehydration, or emaciation.

Impact of body weight

Early identification of patients at nutritional risk minimizes the detrimental effects of weight loss or adverse consequences of obesity, both of which have been associated with poor outcome. In a retrospective analysis, Deeg et al. [7] examined the effect of body weight on clinical outcome in 2238 transplant recipients in the first 150 days post-transplant. Patients who were less than 95% of ideal weight had a significantly poor prognosis, with an even poorer prognosis in patients weighing less than 85% of ideal [7]. Using a patient-generated-subjective global assessment tool, Horsley et al. [8] observed that malnourished HCT recipients had a longer length of hospital stay. Obesity also appears to influence outcome in the HCT population, as adult and pediatric transplant recipients with a high body mass index (BMI) have worsened survival outcomes [9,10].

Integrative medicine

The use of complementary or integrative therapies by transplant patients is becoming increasingly prevalent. Patients often pursue these therapies to help their improve sense of wellbeing, reduce anxiety, and provide a sense of control. Bruemmer et al. [11] found that upon arrival for HCT, a high percentage of patients used supplemental vitamins and minerals.

The use of non-conventional therapies, such as herbal and megavitamin therapy, poses great concern for the transplant population. Dietary supplement preparations may alter the therapeutic effect of medications, chemotherapeutic agents, and radiation, thereby impacting treatment effectiveness and adding a variable to the treatment protocol evaluation [12]. Potential contamination of preparations derived from plants poses the risk of bacterial, fungal, or parasitic infections in immunocompromised patients. As supplements are not regulated by the US Food and Drug Administration (FDA), dosages may vary widely and products may contain unlisted contents. Some preparations may be contaminated with toxic metals, drugs, or other botanicals with a drug-like effect, which could result in serious health risks.

Screening for the use of supplements is an important component of the baseline nutrition assessment for all transplant patients; those patients taking supplements should be advised to discontinue all such remedies in the pre-transplant evaluation period. A standard iron-free multivitamin and mineral supplement is recommended for all patients to avoid micronutrient deficiencies that may develop due to either drug-induced vitamin and mineral wasting or changes in eating patterns that may result in a micronutrient deficiency. Supplementation with all antioxidants and other vitamins should not exceed the Dietary Reference Intakes as a precaution to avoid potential interaction with chemotherapeutic agents. Supplements associated with serious adverse effects that are contraindicated during HCT are listed in Table 99.1 [3].

Nutrient and fluid requirements

Guidelines for dosing nutrient and fluid needs are outlined in Table 99.2 [2]. Individual requirements, however, vary in the setting of organ dysfunction. Of paramount importance throughout the transplant course is the provision of adequate oral and/or IVF for maintenance of hydration status.

Table 99.1 Contraindicated supplements during HCT

Alfalfa
Botanicals containing pyrrolizidine alkaloids (borage, coltsfoot, comfrey, groundsel, valerian, maté tea)
Botanicals that react with drugs utilizing the cytochrome P450 enzyme system (echincea, garlic, ginkgo, ginseng, grape seed, kava)
Chaparral
Chinese/oriental herbs
DHEA
Dieter's tea
Ephedra
Laetrile
Licorice root
Lobelia
L-Tryptophan
Pau d'arco
Pennyroyal
Sassafras
St. John's wort
Yohimbe
Yohimbine

Source: adapted from Macris (ed.) 2012 [3]. Reproduced with permission of Seattle Cancer Care Alliance.

Electrolyte and metabolic complications may alter nutrient needs. Table 99.3 [3] lists nutrition intervention strategies for common complications observed during HCT.

Nutrition support

The goal of nutrition support is to provide sufficient exogenous energy substrates, especially during regimen-related toxicities and GVHD, to minimize the loss of lean body mass, and to avert morbidity associated with malnutrition.

Oral diet

Oral feedings are indicated for patients with a functional GI tract. Historically, HCT recipients were treated with GI decontamination in ultraisolation environments and served diets of varying microbial content ranging from "sterile" to "cooked food only," in attempts to minimize the introduction of pathogenic organisms [13]. A survey by Smith and Besser [14], involving 156 institutions belonging to the Association of Community Cancer Centers, reported that most transplant centers still utilize some type of neutropenic diet for their HCT population.

Although several studies have examined the role of diet and infectious risk, the protective benefit of a low microbial diet against infection has not been established [1]. DeMille et al. [15] examined the effect of a neutropenic diet on infection in a group of 28 adult patients and reported no significant differences in rates of febrile admissions or positive blood cultures between compliant and non-compliant patients. A study by Moody et al. [16] compared the neutropenic diet with the FDA-approved food safety guidelines in children undergoing aggressive chemotherapy regimens and observed that infection rates were similar between the groups.

Although more research about the protective benefits of a neutropenic diet for the HCT population is needed before its effectiveness can be established, present practice is to implement a diet that restricts high-risk foods and safe food handling [1]. An example of a diet for immunocompromised transplant patients is presented in Table 99.4. In general, autologous patients follow the diet during the first 3 months after transplantation; allogeneic patients follow the diet until all immunosuppression has been discontinued.

When oral intake is not adequate in meeting nutrient needs, EN in the form of tube feedings or PN support may be indicated.

Table 99.2 Nutrient and fluid requirements

Nutrient	Requirement	Altered requirements
Calories	Adults: Basal needs × 1.3–1.5 *or* 30–35 kcal/kg Adolescents and older children: Basal needs × 1.4–1.6 Young children: Basal needs × 1.6–1.8	Increase: Immediate post-transplant period due to metabolic stress induced by the preparative regimen, fever, infections Decrease: Engraftment; absence of metabolic complications; limited physical activity
Protein	Adults: 1[a]–1.5 g/kg/day 15–18 years: 1.8 g/kg/day 11–14 years: 2 g/kg/day 7–10 years: 2.4 g/kg/day Birth–6 years: 2.5–3 g/kg/day	Increase: Immediate post-transplant period; corticosteroid treatment; CRRT Decrease: Renal or hepatic dysfunction
Carbohydrate	50–60% total energy support Dextrose load: Adults: <5 mg/kg/min Adolescents: 7–10 mg/kg/min Children: ≤15 mg/kg/min	Decrease: Lower dextrose PN or hydration fluid concentration with pre-existing diabetes or hyperglycemia Modify oral carbohydrate intake when insulin required; provide diabetes education
Fat	Minimum dose: 6–8% total calories Maximum dose: 40% total calories	Increase: When providing lower dextrose PN concentrations Decrease: Hyperlipidemia
Fluids	1–10 kg: 100 mL/kg/day 11–20 kg: 1000 mL + 50 mL for every kg >10/day 21–40 kg: 1500 mL + 20 mL for every kg >20/day >40 kg: 1500 mL/m^2 BSA	Increase: fever; excessive GI losses; hypermetabolism; high-output renal failure; nephrotoxic medications Decrease: Compromised liver, cardiac or pulmonary function; iatrogenic fluid overload
Vitamins	Parenteral: standard adult and pediatric packages Extra vitamin C to promote tissue recovery after cytoreductive therapy: <31 kg: additional 250 mg/day ≥31 kg: additional 500 mg/day Oral: after PN discontinued, oral vitamin-mineral supplement without iron	Increase: Vitamin D in presence of low serum 25-OH-vitamin D levels: <20 ng/mL: 50,000 units weekly for 8 weeks, followed by 1000–2000 units/day <30 ng/mL or steroid therapy: 1000 units/day Decrease: Discontinue extra vitamin C if serum ferritin >1000 μg/L CRRT: Oral: Standard renal vitamin Parenteral: ½ dose standard vitamin package + water-soluble vitamins; evaluate need for fat-soluble vitamin replacement
Trace minerals and electrolytes	Parenteral: standard adult and pediatric packages Typical initial PN additives per liter: 30 mEq sodium chloride 25 mEq potassium chloride 15 mEq potassium phosphate 8 mEq calcium gluconate 16 mEq magnesium sulfate Oral: after PN discontinued, oral vitamin–mineral supplement without iron	Electrolyte needs are frequently higher owing to food–drug interactions (Table 99.3); serum electrolytes should be monitored daily during PN and 2–3 times weekly in the ambulatory clinic; adjust IV or oral supplementation as indicated Increase: Calcium during corticosteroid therapy or documented osteoporosis: 1500 mg/day for adults and older children 1000–1200 mg/day for younger children Zinc with large-volume diarrhea: 1 mg/100 mL stool output Decrease: Iron supplementation contraindicated Eliminate copper and manganese from PN in presence of hepatic dysfunction

BSA: body surface area; CRRT: continuous renal replacement therapy; GI: gastrointestinal; IV: intravenous; PN: parenteral nutrition.

Enteral nutrition

When the GI tract is functional and intact, EN is the preferred method of nutrition support [1]. During HCT, EN support is appropriate for patients who are malnourished and who are anticipated to be unable to ingest and/or absorb adequate nutrition for a prolonged period. Historically, barriers such as thrombocytopenia, GI complications, mucositis or esophagitis, lack of enteral access, and patient acceptance precluded the use of enteral feedings in the transplant population, so PN was standard supportive care [17]. In recent years, however, EN has attracted more attention owing to the need to reduce costs and the desire to mitigate infection risk, often associated with PN [6]. The benefits of EN support include maintenance of mucosal gut integrity with stimulation of mucosal repair, decreased incidence of hyperglycemia, maintenance of normal gut barrier function, decreased risk of infection, and decreased cost [6,17]. A recently published study by Seguy et al. [18] suggested that provision of EN support may have a protective effect against the development of grade III–IV acute GVHD and also on transplant survival.

Candidates for EN support in the transplant setting include patients who receive non-myeloablative or reduced-intensity conditioning regimens with poor oral intake or malnutrition or those undergoing a myeloablative conditioning regimen with a lower GI toxicity profile [6,19]. The use of EN may also be an option for patients receiving a low-risk transplant (autologous or matched related donor), those with long-term eating problems following engraftment, resolution of conditioning-related mucositis and esophagitis, and adequate platelet count (as defined by the institution) [6,19]. Finally, EN may be appropriate for patients with chronic oral or esophageal GVHD or ongoing weight loss when insufficient nutrients are consumed for weight maintenance.

Although EN may be a viable form of nutrition support, case series or pilot studies suggest formidable challenges in utilizing nasoenteric or enterostomy feeding tubes. Sefcick et al. [20] reported tube displacement by vomiting and aspiration in a pilot study of 15 allogeneic transplant patients. Lenssen et al. [21] observed similar results of vomiting with dislodgement of feeding tubes, despite scheduled antiemetics, in a cohort of eight transplant recipients. Post-transplant gastroparesis was described by Eagle et al. [22], with allogeneic patients at higher risk of delayed gastric emptying compared with the autologous population (26% vs. 0%; $p < 0.0001$). Poor tolerance of rapid advancement of feeds, as indicated by diarrhea and abdominal pain, when transitioning from PN after myeloablative conditioning is another complication associated

Table 99.3 Nutrition intervention strategies for common metabolic complications

Measure	Indicator	Nutritional intervention
Potassium	<3.5 mEq/L related to: Correction of hyperglycemia GI losses Medications: amphotericin, corticosteroids, diuretics, foscarnet Refeeding syndrome/anabolism >5.5 mEq/L related to: Excessive supplementation (e.g. resolving potassium wasting) Medications: cyclosporine, potassium-sparing diuretics, tacrolimus Renal insufficiency Tumor lysis syndrome	Oral: Develop a diet plan that includes high-potassium foods and fluids Oral supplementation IV: Supplement in PN, IVF, or separate IV infusion up to a maximum 20 mEq/h (0.3 mEq/kg/h for children) without a cardiac monitor; maximum 10–15 mEq/h in ambulatory care Develop a diet plan that includes low-potassium foods and fluids Discontinue all potassium supplementation
Magnesium	<1.8 mEq/L related to: Diarrhea/steatorrhea Malabsorption syndromes Medications: amphotericin, cyclosporine, foscarnet, loop diuretics, prior cisplatinum therapy, tacrolimus Refeeding syndrome Severe malnutrition >2.4 mEq/L related to: Discontinuation of a magnesium wasting medication Excessive supplementation Renal insufficiency	Oral: Develop a diet plan that includes high-magnesium foods and fluids Oral supplementation IV: Supplement in PN, IVF, or separate IV infusion, not to exceed 24 mEq/h (1 mEq/kg/h for children) Discontinue all magnesium supplementation; decrease IV before oral supplement
Phosphorus	<2.5 mg/dL (<4.5 mg/dL for children) related to: Medications: corticosteroids, cyclophosphamide, foscarnet, sirolimus Mineralocorticoid deficiency Refeeding syndrome Renal acidosis >4.5 mg/dL (>6.0 mg/dL for children) related to: Excessive phosphorus intake Multiple myeloma Renal failure Tumor lysis syndrome	Oral: Develop a diet plan that includes high-phosphorus foods and fluids Oral supplementation IV: Supplement in PN, IVF, or separate IV infusion up to 7 mEq/h in ambulatory clinic or 5 mEq/h for home administration Oral: Develop a diet plan to limit foods high in phosphorus (*not recommended for extended periods owing to the possibility of decreased intake of other nutrients such as protein and calcium*) Phosphate binders with meals Discontinue all phosphorus supplementation
Calcium	<8.9 mg/dL (corrected for abnormal serum albumin) related to: Diarrhea Hyperphosphatemia Hypoalbuminemia Hypomagnesemia Medications: corticosteroids, foscarnet Vitamin D deficiency >10.2 mg/dL (corrected for abnormal serum albumin) related to: Hyperparathyroidism Multiple myeloma Renal failure Tumor lysis syndrome	Correct serum level in presence of hypoalbuminemia Check ionized serum calcium level Provide IV calcium gluconate at starting dose of 9 mEq (0.45 mEq/kg for children <20 kg) Discontinue all calcium supplementation Provide sodium-containing IVF as necessary If on PN, remove calcium; if alkalotic, add chloride
Sodium	<135 mEq/L (corrected for abnormal serum glucose levels) related to: Diabetes insipidus Excess GI losses Excessive IV or fluid/free water intake Fluid retention Hyperglycemia Medications: cyclophosphamide, cyclosporine, furosemide Syndrome of inappropriate antidiuretic hormone >145 mEq/L related to: Medications: corticosteroids, foscarnet	Oral: If fluid overloaded, develop a diet plan that limits total fluid intake to 1500 mL × BSA or less as indicated IV: If excessive sodium losses, consider normal saline infusion Oral: Decrease dietary sodium intake IV: Adjust sodium additive in PN; change to low-sodium containing IV hydration
Glucose	≥180 mg/dL on two or more episodes related to: Medications: corticosteroids, cyclosporine, tacrolimus Excessive dextrose load Patient or family history of DM Sepsis	Oral: Nutrition education regarding appropriate meal and snack choices, including monitoring intake of simple carbohydrate foods and fluids; if on insulin therapy, assess need for carbohydrate counting IV: During PN: decrease total energy support if in excess of needs; adjust macronutrients to lower carbohydrate load while maintaining adequate energy support by adjusting protein and fat load as indicated; attempt continuous infusion of macronutrients throughout 24-hour period Initiate PN at a lower dextrose concentration Add insulin to PN; an insulin drip may be necessary if serum glucose is labile or refractory in increasing insulin in PN If on IVF: change to dextrose-free hydration Endocrinology consult
Triglyceride	Non-fasting or fasting level of >350 mg/dL related to: DM Excessive dextrose support Familial hyperlipidemia Hepatic dysfunction Medications: corticosteroids, cyclosporine, hormones, contraceptives Obesity Pancreatitis Sepsis	Oral: Develop a diet plan that may include achieving desirable body weight, limit simple carbohydrate and fat intake; increase omega-3 fatty acid intake; no alcohol intake IV: Provide IV lipids at 4–8% total calories If serum triglycerides >1000 mg/dL, hold lipids and cycle PN for mobilization of body stores of essential fatty acids Endocrinology consult

BSA, body surface area; DM, diabetes mellitus; GI, gastrointestinal; IV, intravenous; IVF, intravenous fluid; PN, parenteral nutrition.

Table 99.4 Diet guidelines for immunosuppressed patients

Food restrictions

- Raw and undercooked: meat (including game), fish, shellfish, poultry, eggs, sausage, bacon
- Raw tofu, unless pasteurized or asceptically packaged
- Luncheon meats (including salami, bologna, hot dogs, ham) unless heated until steaming
- Refrigerated smoked seafood typically labeled as lox, kippered, nova-style, or smoke or fish jerky (unless contained in a cooked dish; pickled fish
- Unpasteurized milk and raw milk products, unpasteurized cheese, and unpasteurized yogurt
- Blue-veined cheeses including blue, Gorgonzola, Roquefort, Stilton
- Uncooked soft cheeses including Brie, Camembert, feta, farmer's
- Mexican-style soft cheese, including queso blanco and queso fresco
- Cheese containing chili peppers or other uncooked vegetables
- Fresh salad dressings containing raw eggs or contraindicated cheeses
- Unwashed raw and frozen fruits and vegetables and those with visible mold; all raw vegetable sprouts
- Raw or unpasteurized honey
- Unpasteurized commercial fruit and vegetable juices
- Well water must be boiled for 15–20 minutes and consumed within 48 hours

with enteral feedings [19]. Finally, weight loss [20], decreased body cell mass [23], and electrolyte and mineral deficiencies [24,25], due primarily to difficulties in maintaining access and in delivering adequate support, are other noted implications associated with EN support.

Experience at our institution suggests that when absolute neutrophil count (>1000/mm^3) and platelet count (>50,000/mm^2) are adequate, nasoenteric and enterostomy feeding tubes may safely be placed [19]. A range of enteral formulas have been necessary depending upon the patient's GI tolerance and organ function. Adult and pediatric semi-elemental formulas, renal formulas, and concentrated formulas, when volume restriction has been indicated, have all been used [2,6]. Mulder et al. [26] also suggested that the combined use of EN with PN support may be an acceptable and cost-effective alternative.

Parenteral nutrition

Historically, PN was standard supportive care for HCT recipients due to the multiple adverse effects of regimen-related toxicities and GVHD, which precluded tolerance to oral feedings or EN; the constant availability of central venous access also made the administration of PN fluids possible. Early studies suggested that PN support during transplantation was associated with improved visceral protein status [27], maintenance of body weight [28], and increased disease-free survival in the allogeneic population [29]. More recent studies, however, have reported conflicting evidence supporting the routine use of PN. The use of PN during transplantation has been associated with complications such as hyperglycemia [30], increased infection risk [31], and thrombocytopenia [32], which may result in greater morbidity and poorer outcome.

To limit these complications, shortening the exposure time of PN support may be strategic in limiting infections or other adverse complications once stem cells have engrafted and regimen-related toxicities have resolved [1]. The clinical decision to discontinue PN, however, should consider the patient's overall nutritional status, severity of GI toxicities, and ability to maintain oral intake. Provision of PN can safely be discontinued, without adverse effects, when patients consume approximately 30% of estimated energy needs, without evidence of malnutrition, malabsorption, or other significant GI toxicities, at time of hospital discharge [33,34]. Discontinuation of PN has also been shown to result in an earlier resumption of oral intake after transplantation [34].

Candidates for PN may include transplant recipients receiving high-intensity conditioning regimens with anticipated severe GI toxicity that precludes adequate intake [19]. The use of PN is also indicated for patients who develop severe intestinal GVHD or other GI toxicities such as high-volume infectious diarrhea, patients who fail to receive adequate nutrition from an enteral route (orally or via tube feedings), and malnourished patients with minimal reserves [1,17].

Even with high-intensity preparative conditioning regimens, however, PN is not uniformly indicated for all patients. Iestra et al. [35] applied standard criteria for malnutrition in oncology patients to determine the appropriate use of PN during HCT: (1) severe malnutrition at admission (serum albumin <3 g/dL or BMI <18.5 kg/m^2), (2) a prolonged period (7–10 days) of minimal oral intake, or (3) clinical weight loss of >10%. Indications for the use of PN differed significantly between treatment groups; PN was required in only 37% autologous patients conditioned without total body irradiation (TBI) versus 92% of patients who received a mismatched allograft [35].

With the advent of reduced-intensity and non-myeloablative conditioning regimens, PN is no longer considered standard supportive care as many of these conditioning protocols are associated with less regimen-related toxicities than standard myeloablative regimens. Diaconescu et al. [36] compared 73 non-myeloablative with 73 myeloablative matched related transplant recipients and found that the greatest difference between the groups was seen in GI toxicities, with no severe mucositis among non-myeloablative patients compared with a 70% incidence of mucositis among ablative patients. A similar study by Topcuoglu et al. [37] showed that mucositis was observed less frequently and with decreased severity and duration in a reduced-intensity conditioning regimen compared with a myeloablative regimen (46% vs. 93%; $p < 0.0001$), resulting in a decreased need for PN (21% vs. 77%; $p < 0.0001$). Other investigators have also documented a significant reduction in the need for PN due to decreased GI injury in reduced-intensity and non-myeloablative conditioning regimens [38,39].

Irrespective of the type of transplant, a major complication of PN is hyperglycemia. Fuji et al. [30] reported an association between the degree of hyperglycemia during neutropenia and an increased risk of complications and non-relapse mortality (NRM). Management of PN-induced hyperglycemia is dependent upon the patient's clinical status, etiology, and institutional practice, with the goal of achieving a glucose level as close to normal as safely possible [19]. Provision of intravenous lipids, with a concomitant decrease in dextrose substrate, may also be used to minimize the development of hyperglycemia that can occur in patients who have sepsis, pre-existing diabetes mellitus, or GVHD treated with glucocorticoids [40]. During episodes of PN-induced hyperglycemia, the nutrition support regimen should be continuously evaluated to ensure that the patient is not being overfed and/or receiving excessive carbohydrate [6].

Intravenous lipids are a necessary component of PN to supply energy and essential fatty acids. While lipids have been implicated as being immunosuppressive, there is not an established increased risk of infection in the transplant population. Lenssen et al. [41] compared the rates of bacteremia and fungemia in autologous and allogeneic HCT patients receiving 6–8% (low dose) or 25–30% (standard dose) of total energy as a 20% lipid emulsion. The results showed that there were no treatment-related differences in incidence or time to first infection or incidence of acute or chronic

GVHD [41]. A review by Arfons and Lazarus [42] suggested that because lipids may alter the immunologic responses of prostaglandins and leukotrienes, they may play a role in decreasing the incidence of acute or chronic GVHD. More research is needed to determine the impact of lipids on the development of GVHD [40].

The management and prevention of PN-induced complications require close monitoring by the clinician. Hagiwara et al. [43] suggested that intervention with a nutrition support team may provide more economical and clinical efficacy with respect to managing clinical complications, such as hyperglycemia.

Glutamine-enriched nutrition support

Over the past two decades, considerable research has been focused on the role of glutamine-enriched nutrition support during HCT to ameliorate gut and liver toxicity [40]. Studies assessing the impact of orally administered glutamine have shown no effect on morbidity or mortality in transplant recipients [44,45]. Patients maintained on glutamine-enriched PN solutions have been reported to have decreased hospital stays, reduced incidence of positive blood cultures [46], and improved lymphocyte recovery [47]. Conversely, two randomized double-blind clinical trials described significantly more relapses in autologous patients receiving parenteral glutamine administration [48,49]. More recent data suggest that additional studies are needed to determine the appropriate dose and timing of glutamine supplementation in the HCT population [50].

Special management problems

HCT recipients experience numerous problems that interfere with adequate nutrient intake and nutritional status. These complications may be associated with the pre-transplant conditioning regimen and include oral and GI sequelae and organ or tissue damage resulting in hepatic, renal, or pulmonary impairment; iron overload and glucocorticoid-induced hyperglycemia are also frequently observed. Moreover, GVHD has its own unique nutritional challenges that impact nutritional status.

Oral/gastrointestinal issues

As nutrition-related effects vary widely between myeloablative, reduced-intensity, and non-myeloablative transplant regimens, recommendations are not universal for all transplant recipients. Myeloablative conditioning regimens often result in toxicities, such as oral mucosal ulceration, that develop within the first month and significantly impact the patient's ability to achieve adequate oral intake, thus necessitating nutrition support. Oral mucositis is a frequent complication of HCT with an incidence as high as 75–99% [51].

Robien et al. [52] observed that patients treated with a TBI conditioning regimen who had methotrexate for GVHD prophylaxis, in addition to a BMI >25 kg/m^2, and methylenetetrahydrofolate reductase 677 TT genotype, were found to have a higher oral mucositis index score. Multivitamin supplementation in these patients showed a trend towards statistical significance as a protective factor for the development of severe mucositis [52].

Novel approaches to preventing mucositis during HCT have included the use of gut-protective therapy and cryotherapy. Palifermin, a humanized keratinocyte growth factor that preserves intestinal barrier function, has been shown to decrease the severity and duration of mucositis, in very mucotoxic regimens, resulting in less need for nutrition support [53]. Cryotherapy has been effective in reducing the severity of grades III–IV mucositis, with a statistically lower use of PN in 40 autologous patients treated with melphalan [54].

Conditioning chemotherapy and TBI decrease and destroy taste receptor cells, resulting in dysgeusia or altered taste sensation, which affects food selection and contributes to poor oral intake [19,55]. Medications, including morphine, antibiotics, tacrolimus, and cyclophosphamide, are also associated with taste alterations [19]. Studies examining taste alterations in HCT patients have shown increased taste thresholds for both salt [56,57] and sour [57,58]. Whereas an early study reported recovery of taste changes by day 30–50 after transplantation [58], a more recent study found that patients continued to report dysgeusia as late as day 90–100 after transplantation [59]. Nutrition management of dysgeusia requires a complete clinical and nutritional evaluation with appropriate nutrition counseling.

Nausea and vomiting are most frequently associated with the preparative conditioning regimen, especially those containing alkylating agents, TBI, and upper intestinal GVHD [3]. Antiemetics are routinely prescribed to prevent and control symptoms, with the goal of allowing patients to continue eating and taking oral medications. With severe GI symptoms, nutrition support may be indicated. Diarrhea is common following high-dose cytoreductive therapy, oral antibiotics, intestinal infections, such as cytomegalovirus enteritis or *Clostridium difficil*e colitis, intestinal GVHD, lactose intolerance, gastric motility agents, and magnesium salts [3,19].

Dietary guidelines for managing oral and GI toxicities associated with HCT are described in Table 99.5.

Sinusoidal obstructive syndrome

The condition of sinuosoidal obstructive syndrome (SOS) is characterized by toxic injury to the sinusoidal and venular epithelium [6]. Clinical symptoms include insidious weight gain, ascites, right upper quadrant tenderness and hepatomegaly; hyperbilirubinemia and renal dysfunction follow [60]. Medical nutrition therapy entails management of sodium and water balance through concentration of PN fluids and medication volumes as well as reduction of both oral and intravenous sodium; continuous renal replacement therapy may be necessary if renal function is compromised [3,60,61]. If hyperbilirubinemia (serum bilirubin rises to >10 mg/dl), biliary excreted tace elements, copper and manganese, should be removed from PN solutions [2]. If hypertriglyceridemia (serum triglyceride >350 mg/dL) develops, the dose of intravenous lipid should be modified to provide 4–8% of total calories to prevent essential fatty acid deficiency [3]. The patient's level of nutrition support should be also assessed to minimize the risk of overfeeding and ensure optimal carbohydrate metabolism as a lower dextrose load may be indicated [3].

Renal complications

Acute kidney injury is a recognized complication of HCT with a prevalence as high as 70% following HCT [62]. Renal compromise ranges from prerenal insufficiency to acute renal failure requiring continuous renal replacement therapy and is associated with an increased risk of morbidity and mortality [62,63]. Nutrition support goals during renal impairment are to minimize uremic toxicity and other metabolic derangements while preventing malnutrition. Nutrition intervention involves maximizing nutrition support within fluid allowance, correcting electrolyte imbalances, and maintaining sufficient intravascular volume [19]. During continuous renal replacement therapy, protein and vitamin needs are altered as shown in Table 99.2.

Table 99.5 Nutrition management of common transplant-related oral and gastrointestinal complications

Indicator	Recommended intervention
Lack of interest in eating due to HCT *Related to:* Anxiety Depression Dysgeusia Food aversion Hepatic disease History of prior eating disorder Lack of interest in food Long period of NPO Upper intestinal GVHD/lymphocytic gastritis	Develop a diet plan that may include small, frequent, low-fat feedings and encourage food experimentation to optimize oral intake Evaluate appropriateness of appetite stimulant
Early satiety *Related to:* Hypomotility of GI tract due to prolonged NPO, conditioning, GVHD Medications: cyclosporine, narcotics Severe ascites Splenomegaly PN	Develop a diet plan that may include small, frequent, low-fat feedings and nutritionally dense fluids to optimize oral intake If prolonged course of PN, trial off or cycle infusion at night Gastric motility agents
Vomiting/nausea *Related to:* Altered salivary secretions Anticipatory nausea and vomiting Dehydration Food aversion GVHD Hepatic disease Medications: cyclosporine, trimethoprim + sulfamethoxazole Systemic infections	Develop a diet plan that may include salty or sour foods; cold, clear liquids; cold solids; small, frequent meals; and low-fat, low-fiber foods to optimize oral intake Scheduled antiemetics including GI motility agents If symptoms are severe, begin PN or postpyloric tube feeding
Dysgeusia/hypogeusia *Related to:* Conditioning regimen, especially TBI Medications Oral infections	Encourage good oral hygiene Develop a diet plan that may include a variety of highly spiced, flavorful foods (if mucositis/esophagitis absent) and food experimentation to optimize oral intake
Xerostomia *Related to:* Conditioning regimen Dehydration Healing mucositis Medications: anticholinergics, methotrexate Oral GVHD	Develop a diet plan that may include high-moisture foods, the use of saliva stimulants (e.g. citric acid beverages, sugarless candy, sugarless gum) to optimize oral intake Additional oral or IV fluids as needed Encourage good oral hygiene Saliva substitute
Mucositis *Related to:* Conditioning regimen Methotrexate Oral GVHD Oral viral infections	Develop a diet plan that may include altered texture/temperature and provides adequate vitamin/mineral supplementation to optimize intake If treatment plan includes high-dose melphalan, consider cryotherapy If oral intake is suboptimal, consider EN or PN support
Esophagitis/odynophagia ***Related to:*** Bacterial overgrowth Conditioning regimen GVHD Infection Mucositis Persistent vomiting Prolonged intubation GERD	Develop a diet plan that may include avoidance of alcohol, spicy foods, high-fat foods, and secretagogues; alteration of texture and temperature of foods as appropriate; and maintenance of upright position postprandially If oral intake is suboptimal, consider EN or PN support Initially antacids, then proton-pump inhibitors or H_2 blocker
Dysphagia *Related to:* Chronic GVHD Poor salivary flow Prolonged intubation Reflux/GERD	Speech pathology swallow evaluation Develop a diet plan that may include alterations of texture and temperature If oral intake is suboptimal, consider EN or PN support
Diarrhea *Related to:* Antibiotics Bacterial overgrowth Conditioning regimen Intestinal GVHD GI infection Lactose intolerance Medications: gastric motility agents, magnesium salts Viral enteritis	Adult: if stool exceeds approximately 2000 mL/day, for several days, place patient NPO Child: If stool exceeds approximately 500 mL/day for several days, place patient NPO Initiate GI diet progression (see Table 99.6) If extended NPO, recommend PN Trial with soluble fiber If lactose intolerant, provided low lactose diet and prescribe lactase enzymes If magnesium-related, modify dose and institute IV magnesium supplementation If suspect related to gastric motility agent, discontinue oral medication and institute IV supplementation Antidiarrheals for mild diarrhea Develop a diet plan that may include low-fat, low-insoluble fiber; low-lactose products and lactase enzyme preparation; avoid GI irritants/stimulants and offending disaccharides
Constipation *Related to:* Drug toxicity: narcotics History of GI dysfunction Inactivity Low-fiber diet Low fluid intake	Develop a diet plan that includes dietary fiber with increased insoluble fiber and fluid intake Encourage physical activity as appropriate Assess need for pharmacological intervention

EN, enteral nutrition; GERD, gastrointestinal reflux disease; GI, gastrointestinal; GVHD; graft-versus-host disease; IV, intravenous; IVF, intravenous fluid; NPO, nothing by mouth; PN, parenteral nutrition; TBI, total body irradiation.

Pulmonary compromise

Pulmonary complications account for significant morbidity and mortality in transplant recipients and are related to infections, regimen-related toxicities, and chronic GVHD [64]. Nutrition intervention for patients who develop transplant-related pulmonary compromise include reducing total sodium intake (oral, intravenous, and medications) and restricting fluids by using concentrated dextrose and amino acid solutions and also lipid emulsions. Assessing the patient's level of nutrient support to minimize the risk of overfeeding is also necessary. Finally, for patients with excessive CO_2 production, adjusting the proportion of energy from carbohydrate and fat may be necessary [3]. Pulmonary insufficiency associated with chronic GVHD may raise metabolic requirements resulting in hypercaloric needs to prevent weight loss and debilitation, so close nutrition monitoring is required.

Iron overload

Iron overload, related to multiple red blood cell transfusions and dyserythropoiesis leading to aberrant hepcidin regulation and increased iron transport by the intestine, is frequently observed during transplantation [65,66]. McKay et al. [66] reported an 88% incidence of elevated serum ferritin concentrations, suggestive of iron overload, in a group of 76 autologous and allogeneic transplant survivors. For this reason, iron supplementation is contraindicated during HCT. If baseline serum ferritin is grossly elevated (i.e., >1000 μg/L), no additional vitamin C, which acts as a pro-oxidant in the presence of free iron (other than what is in the standard parenteral or oral vitamin supplement), should be provided to minimize iron-induced organ damage [3].

Glucocorticoid-induced diabetes

Hyperglycemia is a common complication of glucocorticoid therapy used in the treatment of GVHD in allogeneic transplant recipients. A retrospective review by Pidala et al. [67] demonstrated that aberrant glucose levels were associated with increased NRM. Recommendations from this study include routine assessment of glycemic control with management in the setting of a multidisciplinary team [67]. The registered dietitian is a vital team member who can provide appropriate nutrition education, especially when glucocorticoids are tapered, as oral intake and insulin needs vary widely.

Acute graft-versus-host disease

Acute GVHD is an inflammatory disease predominantly targeting the skin, liver, and GI tract. Clinical GI symptoms associated with acute GVHD include nausea, vomiting, anorexia, early satiety, and/or diarrhea. Diarrhea related to GVHD is multifactorial in etiology and includes villous atrophy, mucosal ulceration, secretory dysfunction, osmotic factors, rapid passage, and pancreatic insufficiency [68]. Secretory, voluminous diarrhea and intestinal bleeding occur in advanced disease [69]. Intestinal losses often result in dehydration, loss of electrolytes, fat, and protein and also intolerance of oral and enteral feeding, necessitating bowel rest and PN support. In addition to immunosuppressive therapy, empiric diet guidelines have been developed as detailed in Table 99.6 [70]. The diet progression for refeeding patients includes bowel rest with PN support, followed by introduction of liquids and solids low in lactose, fiber, acid, and fat, and expansion of the diet as tolerated [70].

Rezvani et al. [71] observed that a change in serum albumin concentration from baseline to initiation of acute GVHD treatment was a predictive biomarker of GVHD severity and mortality in 401 allogeneic transplant recipients following a reduced-intensity conditioning regimen. A serum albumin level ≥ 0.5 g/dL decrease from baseline value predicted the subsequent development of grades III and IV acute GVHD with a sensitivity of 69% and a specificity of 73% [71].

Acute GVHD may also involve the oral mucosa, with symptoms ranging from mild pain to frank mucosal ulceration [19]. Patients with severe oral GVHD may require EN or PN support to maintain lean body mass if an adequate oral intake cannot be sustained.

Initial treatment of patients with acute GVHD often includes glucocorticoid therapy. Long-term exposure to glucocorticoids, however, may result in infectious, metabolic, and other adverse complications, thereby increasing transplant-related morbidity and mortality [72]. Lee et al. [73] reported that >40% of patients with acute GVHD treated with high-dose glucocorticoids develop

Table 99.6 Gastrointestinal diet progression: the table is an idealized progression and serves as a guideline rather than a rigid regimen

Phase	Clinical symptoms	Diet	Clinical symptoms of diet intolerance
1. Bowel rest	GI cramping Large-volume watery diarrhea Depressed serum albumin Severely reduced transit time Small bowel obstruction or diminished bowel sounds Nausea and vomiting	Oral: NPO IV: Stress energy and protein requirements	
2. Introduction of oral feeding	Minimal GI cramping Diarrhea <500 mL/day Improved transit time Infrequent nausea and vomiting	Oral: Isotonic, low-residue, low-lactose fluids IV: As for Phase 1	Increased stool volume or diarrhea Increased emesis Increased abdominal cramping
3. Introduction of solids	Minimal or no GI cramping Formed stool	Oral: Allow introduction of solid foods containing minimal lactose, low fiber, low fat, low total acidity, no gastric irritants IV: As for Phase 1	As in Phase 2
4. Expansion of diet	Minimal or no GI cramping Formed stool	Oral: Minimal lactose, low fiber, low total acidity, no gastric irritants; if stools indicate fat malabsorption: low-fat diet IV: As needed to meet nutritional requirements	As in Phase 2
5. Resumption of regular diet	No GI cramping Normal stool Normal transit time Normal serum albumin	Oral: Progress to regular diet; acid foods with meals, fiber-containing foods, lactose-containing foods; order of addition will vary depending on individual tolerances and preferences; patients without steatorrhea should have fat restriction slowly liberalized IV: Discontinue when oral intake meets nutrient needs	As in Phase 2

myopathy. For these patients, a resistive exercise program has been shown to be beneficial in increasing muscle strength [74]. Alterations in nutrient needs during glucocorticoid therapy are outlined in Table 99.2 [2].

Long-term complications and management

As advances in technology and supportive care measures have improved, the number of long-term HCT survivors continues to increase. With this growth, a greater emphasis is now being placed on treating long-term complications [2].

Chronic graft-versus-host disease

Chronic GVHD, a multisystem disease involving inflammation and fibrosis, has a somewhat different presentation to the acute form and often occurs later in the transplant course. However, an "overlap" syndrome has been recognized in which diagnostic or distinctive features of both chronic GVHD and acute GVHD appear together [75].

Chronic GVHD is a separate entity from acute GVHD and, like acute GVHD, can affect nutritional status. A retrospective review of 192 allogeneic transplant recipients found that weight loss, weight gain (due to glucocorticoid therapy), oral sensitivity, xerostomia, stomatitis, anorexia, and reflux symptoms were among the nutritional sequelae observed at 1 year after transplantation [76]. Kyle et al. [77] found that patients with chronic GVHD had a significantly lower lean body mass with a higher body fat index at 6 and 12 months after transplantation.

Oral manifestations, as described above, are common in patients with chronic GVHD, leading to inability to chew and swallow food properly and affecting diet variety. Texture modification, including liquid, puréed, or soft foods, is indicated during dysphagia with referral to a speech pathologist for swallowing evaluation. With severe symptoms, esophageal dilatation may be necessary. If oral and/or esophageal symptoms preclude adequate calorie–protein intake for weight maintenance, gastrostomy tube placement for EN support is appropriate.

Diarrhea and nutrient malabsorption, associated with chronic GVHD, can result from abnormal intestinal mucosa, intestinal bile salt deficiency, pancreatic exocrine insufficiency, and bacterial overgrowth [78]. Histologic changes in pancreatic ductular tissue may result in pancreatic insufficiency with subsequent steatorrhea [65]. Diagnosis of fat malabsorption may be confirmed through screening tests such as fecal elastase (<100 μg/g) or serum trypsinogen (<20 ng/ml) [3,65]. Most patients respond to supplementation with oral pancreatic enzymes and dietary fat restriction; the use of products containing medium-chain triglycerides may also be indicated [3,78].

Growth and development issues

Impaired growth and development frequently occur in pediatric patients following HCT. Myeloablative conditioning regimens influence endocrine function. With cyclophosphamide alone, thyroid function, growth rates, and pubertal maturation are normal. Decreased growth velocity, growth hormone deficiency, and delayed onset of puberty have been observed in children treated with busulfan or TBI [79]. All children undergoing HCT should have regular evaluations to detect endocrine dysfunction. Initiation of appropriate hormonal therapy, when abnormal endocrine function is detected, may improve growth and development.

Metabolic syndrome

Metabolic syndrome, characterized by obesity, hyperlipidemia, hypertension, and glucose intolerance, is becoming more prevalent in both adult and pediatric transplant survivors. Majhail et al. [80] reported a 49% prevalence of metabolic syndrome in 86 transplant survivors more than 1 year after transplantation compared with a prevalence of 30% in controls selected from the 2005–2006 National Health and Nutrition Examination Study database. Annaloro et al. [81] also reported a high incidence of metabolic syndrome in a cohort of 85 patients who were over 5 years after autologous and allogeneic HCT. Chow et al. [82] showed a statistically significant difference in the incidence of cardiometabolic traits, including central adiposity, hypertension, insulin resistance, and dyslipidemia in childhood survivors transplanted for acute lymphoblastic leukemia compared with controls ($p = 0.02$). Increased serum C-reactive protein and leptin levels with decreased adiponectin, suggestive of underlying inflammation and increased visceral fat, were also observed in the survivors [82]. In general, pediatric HCT survivors are more likely to develop diabetes [83] and hypertension [84] than the general population and should be monitored throughout adulthood. Ongoing dietary surveillance and referral to a registered dietitian for nutritional counseling to address contributing dietary factors to metabolic syndrome are appropriate.

Osteoporosis and alterations in vitamin D status

Osteoporosis is a recognized complication of HCT with a prevalence as high as 50% as early as 1 year after transplantation [85,86]. Factors such as chemotherapy, TBI exposure, calcineurin inhibitors, and glucocorticoids all affect bone loss [87]. Prevention and management of osteoporosis includes calcium and vitamin D supplementation. Calcium requirements vary by age and vitamin D needs are typically based on serum levels (Table 99.2). Strategies to improve bone density after transplantation include regular weight-bearing and muscle strengthening exercises [3,87]; bisphosphonate therapy, in conjunction with calcium and vitamin D supplementation, has also been reported to improve bone mineral density [88].

Vitamin D deficiency and insufficiency are common following HCT in both adult [89] and pediatric transplant recipients [90], and current research is examining the relationship between vitamin D status and GVHD. Some researchers speculate that low serum vitamin D levels may play a role in the development of GVHD due to alterations in T-lymphocyte regulation and function [91]. Further studies are needed, however, to determine the impact of vitamin D supplementation on GVHD.

Conclusion

In HCT, an aggressive treatment that results in multiple acute and long-term nutritional challenges, nutrition support has been a life-preserving modality. The registered dietitian plays a key role in recommending and implementing nutrition intervention strategies for these complex patients. Ongoing nutrition assessment and monitoring are essential in this highly technical and rapidly evolving form of therapy.

CHAPTER 100

Pain Management

Noelle V. Frey and Jonathan R. Gavrin
University of Pennsylvania, Philadelphia, PA, USA

Introduction

Patients who receive hematopoietic cell transplantation (HCT) may suffer pain of varying etiologies and severity (Table 100.1). This chapter defines the neurophysiology and pharmacology of pain; what is meant by "pain;" what factors lead a patient to experience and suffer pain; what physical, psychological, environmental, and pharmacologic factors influence the amount of pain and suffering; how this compendium of pain and suffering can be evaluated; and the different means by which pain and suffering can be relieved in the HCT recipient.

Anatomy and physiology of pain

Classically, pain begins with tissue damage (nociception), the type and location detected by peripheral nerves and then signaled to the brain. Our understanding of the neurophysiology and neurochemistry of nociceptive damage detection, transmission to the central nervous system (CNS), and CNS processing to produce the clinical phenomenon of pain, is far from perfect. Our understanding of how the CNS may be influenced by pharmacologic or non-pharmacologic means to suppress nociception and reduce pain also is imperfect. A summary of the known neurophysiology and neuropharmacology of nociception and pain is helpful in understanding clinical management of the HCT patient.

Ascending nociceptive systems

All body tissues possess nociceptors (neural structures that detect tissue damage) that are activated by physical stimuli or by algogenic (pain-producing) substances released when there is tissue injury. Alternatively, nociceptors may be sensitized by algogenic substances, resulting in noxious activation by normally innocuous stimuli, for example, light touch in the presence of inflammation. Nociceptors signal to the spinal cord through fast-conducting Aδ fibers, or slow-conducting C fibers in peripheral nerves, which enter the neuraxis and synapse through dorsal horn cells (Figure 100.1). Dorsal horn cell axons cross the midline and ascend cephalad in the spinothalamic tracts. Information from the fast Aδ fibers ascends rapidly, with no intermediate synapses, to the thalamus, and hence to the cerebrum. Information from the slow C fibers ascends through a number of different synapses, notably to the limbic system, before reaching the thalamus and cerebrum. The C fiber/limbic system synapses initiate the emotional responses to pain [1].

Modulation of nociceptive traffic

Afferent nociceptive transmission is not "hard wired" – signals do not progress to the cerebrum unimpeded and unimpedable. With evolving neurophysiologic knowledge, it has been recognized that afferent transmission may be modulated, as hypothesized in the "gate control theory" of pain [2,3]. This theory states that there are various "gates" within the nervous system that may be opened, or closed, to nociceptive transmission by a variety of processes. The "gating" concept is a useful tool when teaching patients and relatives about pain relief techniques. A basic understanding of this physiology helps patients and family members understand that active interventions, pharmacologic and non-pharmacologic, are essential to obtain optimal pain relief.

Afferent nociceptive transmission can be enhanced or, more importantly, inhibited by the following:

1. Modification of the peripheral nociceptor signaling. Algogenic substances [prostaglandins, serotonin (5-hydroxytryptamine, or 5-HT), substance P, bradykinin] can activate or sensitize peripheral nociceptors; anti-inflammatory medications [aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs)] can oppose such effects.
2. Inhibition of nociceptive transmission in the dorsal horn by non-noxious peripheral stimulation. Rubbing, heat, cold, or electric stimulation peripherally activates sensory afferent fibers that synapse with dorsal horn cells to inhibit nociceptive transmission.
3. Inhibition of dorsal horn nociceptive transmission by the descending nociceptive modulating system. This process originates in the periaqueductal gray matter of the hindbrain (Figure 100.1). The neurotransmitters of this system include 5-HT, norepinephrine (NE), and endogenous opioid (morphine-like) substances, among others. The descending modulatory system can be activated to produce pain relief by learned behavioral or cognitive strategies, or by pharmacologic agents that either mimic endogenous neurotransmitters (e.g. opioids) or stimulate activity of the system {e.g. tricyclic antidepressants (TCAs) [4] and, probably, serotonin–norepinephrine reuptake inhibitors (SNRIs) [5]}.

The clinical phenomenon of pain

The neurophysiology and neuropharmacology described so far deal only with physiologically demonstrable phenomena. The experience of pain clearly is more than neurophysiology, encompassing the subjective interpretation and expression of the neurophysiologic phenomenon.

Table 100.1 Common sources of pain in bone marrow transplantation

Etiology	Examples
Infiltration from primary disease	Bone pain Fractures Soft tissue of visceral pain
Hematopoietic stem-cell mobilization	Bone or joint aching
Chemotherapy or irradiation	Mucositis Cutaneous burns Peripheral neuropathies
Graft-versus-host disease	Skin irritation Gut cramps Oropharyngeal pain
Immunosuppressive drugs	Peripheral neuropathies Joint aching Long bone pain Osteopenic bone fractures
Infection or viral activation	Shingles from herpes zoster Postherpetic neuralgia Cytomegalovirus gut pain
Diagnostic and surgical procedures	Bone marrow aspiration Lumbar puncture Postlumbar puncture headache Line placement Tissue biopsies
Pains unrelated to disease	Headache Low back pain Myalgias from inactivity

What is pain?

Pain is defined as a multidimensional experience [6]. The degree to which an individual feels pain, suffers from pain, and complains of pain is influenced by a number of factors, in addition to tissue damage/nociception. The model depicted in Figure 100.2 [7] is helpful in conceptualizing these components. Nociception is the detection of tissue damage by sensory transducers, and the signaling of this information to the brain. Processing of nociceptive information by the CNS results in the human experience of pain, which is both sensory and affective (feeling). Suffering, the negative cognitive and emotional responses to pain, can be heightened by pain-independent emotional factors, such as fear, anxiety, and depression, that may impact the HCT patient [8]. The compendium of nociception, pain, and suffering, which are subjective, personal, and unmeasurable, emerge to be expressed as pain behaviors. Observations of pain behaviors, including report of pain and inhibition of activity, constitute the raw data that allow the diagnosis of the source of pain and estimation of the magnitude of suffering.

Pain and suffering in the HCT patient

When an HCT patient complains of pain, the most common circumstance is one of obvious tissue damage, such as in oropharyngeal mucositis (OPM). Patients may also complain of pain with little evidence of tissue damage (neuropathy). Irrespective of its source, nociceptive information is processed identically by the CNS, and in all cases the patient feels pain, suffers, and exhibits pain behaviors.

Some patients have easily observed pathology, such as an erythematous and ulcerated mucosa in the mouth, but complain of little pain and appear to suffer little. Other patients have little or no evidence of tissue damage yet complain of much pain and suffer a great deal. What can a clinician make of these two disparate situations? Is the first patient really in pain and really suffering, but not telling anyone? Is the second patient imagining or faking pain? Both explanations are plausible, but unlikely. The fact is, the relationship between nociception, pain, suffering, and pain behaviors is

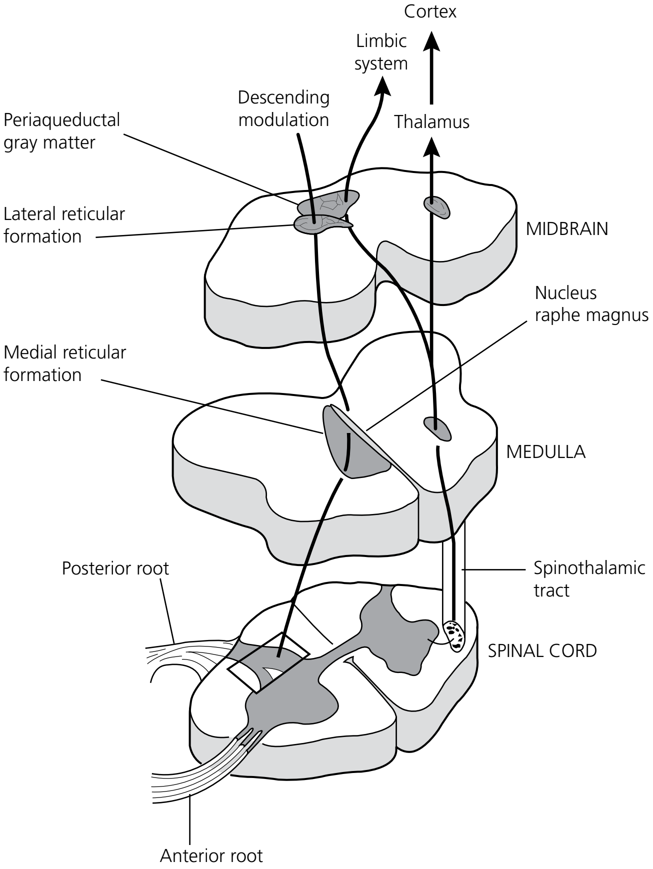

Figure 100.1 Nociceptive information is carried to the spinal cord in Aδ and C fibers. The nerves enter the dorsal horn, where they synapse with second-order neurons that cross the midline of the cord at about the entry level and ascend in the spinothalamic tracts. The Aδ-derived information goes on a fast track directly to the thalamus. The C fiber-derived information reaches the thalamus later, having synapsed in the limbic system. The descending nociceptive afferent modulating system originates in the periaqueductal gray matter. It projects through the nucleus raphe magnus down to the posterior horn, where it has a modulatory effect on the afferent nociceptive traffic.

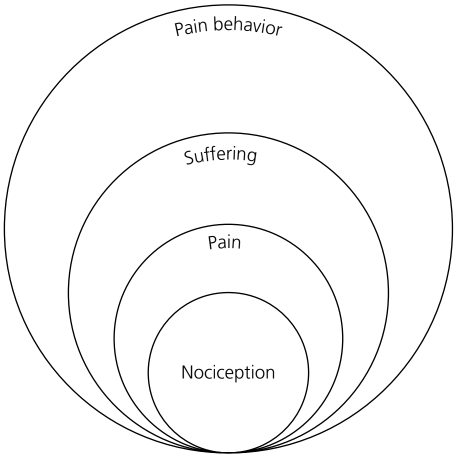

Figure 100.2 A schema of the various aspects of the human pain experience.

not a fixed one. A number of correlates, in addition to physiologic and pharmacologic factors, influence how much patients feel, suffer and complain of pain. Among these correlates are the following:

1 The meaning of the pain. Pain from a known or predictable source often results in less suffering and fewer complaints than pain from an unknown, potentially threatening source.
2 The circumstances in which the pain occurs. A simple pain problem, such as toothache, may result in more suffering and complaints in a patient undergoing HCT than the same pain experienced in normal circumstances.
3 The patient's style of coping with adversity. This style is influenced by social and cultural factors. At one end of the spectrum are those who tough it out and never call for help; at the other end are those who call for help at the first sign of adversity.
4 Emotional state. Fear or anxiety can lead patients to be hyperattentive to sensations. Similarly, depression often reduces activities and increases attention to discomforts.
5 Previous experience with pain. Experience with chemotherapy may serve to reassure patients that current experience is "normal" and will resolve. An inexperienced patient may be thinking, "How can I feel so bad and possibly be doing OK?"
6 Previous exposure to CNS-active pharmacologic agents (analgesics, anxiolytics, or alcohol). These agents may directly influence CNS processing of nociception. If a patient is opioid tolerant or has extensive exposure to alcohol, opioid dosing needs may be higher than average. Usage patterns may also reflect the patient's style of coping with adversity, perhaps to escape into a "pharmacologic fog."

It is well to remember that, regardless of the source, all patients have cognitive and processing components to their pain. Remember the phrase "no brain, no pain." If it is not processed in the brain, it is not felt. Most HCT patients have a nociceptive source of their pain, onto which the cognitive and processing components are grafted.

Assessment of pain and treatment efficacy

History

Some patients will have histories suggesting they are at risk of having significant pain problems or may have difficulty obtaining pain relief. Significant historical factors include:

1 active pain problems related or unrelated to the patient's disease or therapies;
2 previous severe pain after surgery or trauma;
3 difficulty in obtaining satisfactory pain control during events in items 1 and 2;
4 non-pharmacologic pain-relieving strategies that the patient uses;
5 analgesics that the patient has used and any problems with them;
6 previous or current significant emotional or affective disorders;
7 previous or current CNS-active substance use (alcohol, opioids, and anxiolytics);
8 the patient's understanding of the current pain, its significance, and likely duration;
9 the patient's preferred mode of dealing with pain (both non-pharmacologic and pharmacologic).

Pain measurement and monitoring

How is one to assess what the HCT patient is experiencing? Much of the system of nociceptive transmitting, processing, and suffering is subjective and not directly observable (Figure 100.2). It is possible to observe and quantify the system's output (complaints of pain) and use that as an approximation. In clinical practice, an HCT patient's pain is what the patient says hurts, in the amount the patient says it hurts. Those caring for HCT patients should accept pain complaints as real, genuine, worthy of attention, and deserving alleviation.

In practice, pain and its impact are monitored by subjective pain scores and observational function scores. The indices used to monitor pain, the effects, and side effects of therapies and medication use should be observed and recorded frequently using a pain assessment tool. Far from feeling burdened by reporting pain and other symptoms on a daily or per shift basis, patients are often relieved that staff are aware of their symptoms. Consistent evaluation assures patients that their experience is recognized and that evaluation is routine, and therefore normal. Uncertainty and unpredictability about what will happen cause the greatest distress for the greatest number of HCT patients [9–11]. Knowledge that the pain is expected, how it is likely to feel, and how long it is likely to last can help patients to endure even extremely difficult circumstances.

Cancer and HCT patients are reluctant to complain and do not know what experiences are "normal" or what should be reported. They will often answer "fine" or "OK" if asked only, "How are you feeling?" Pain scores and ratings can be used as "objective" quality assurance tools to determine the need for further evaluation or change in treatment. Pain above the equivalent of a score of 3 or 4 (on a scale of 0–10) probably indicates a need to improve pain treatment because the pain likely will substantially disrupt function [12], although in chronic pain patients a more sophisticated rating scale may prove to be more helpful [13]. Even temporary pain should not exceed a score of 6 without mandating further evaluation or additional pain treatment methods [12–15]. The Joint Commission mandates pain assessment as the "fifth" vital sign; pain scores of 5 or above strongly suggest the need for active intervention [16].

Pain scales

Adults and children from about the age of 7 years can report with scales as seen in Figures 100.3, 100.4, and 100.5:

1 Numerical rating scales use scores from 0 = "no pain" to 10 = "pain as bad as can be." It can be helpful the first time with a patient to use a few familiar examples such as: "When you think of a headache you have had in your lifetime, can you remember how it felt?" (Help the person think of a pain he or she remembers.) "When you think of that pain, where would it be on a scale from no pain which is a 0 to pain as bad as anyone could possibly have, which is a 10?" Further help can be offered by saying: "Many people think of 1, 2, or 3 as milder pain; of 4, 5, or 6 as moderate pain; of 7, 8, or 9 as severe pain; and of 10 as being the most extreme pain anyone could ever have." If the patient is still unable to use the scale for cognitive or cultural reasons, the addition of faces, as in Figure 100.4, can be helpful. Numerical scales can be given orally or on paper, as seen in Figure 100.3. In general, these numerical scales are easy to use and record. This scale is favored by clinicians and researchers [14,17].
2 Categorical scales use descriptive words from "no pain" to "extremely severe pain." Such scales are well understood by patients, but are difficult to record or to use to track pain and treatment success.
3 Visual analogue scales. These are 10-cm lines anchored at one end with "no pain" and at the other end with "pain as bad as can be." Patients make a mark at any point along the scale to indicate pain intensity. These scales require measurement of the line in millimeter increments after the patient completes the written scale.

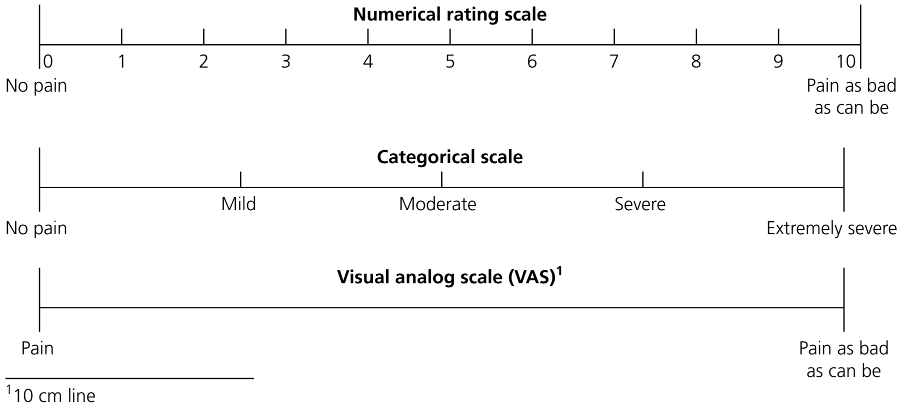

Figure 100.3 Self-report scales for assessing pain in adults. The numerical rating scale is used most frequently.

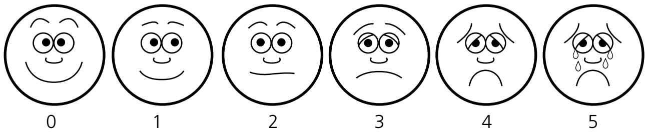

Figure 100.4 A "faces" scale used to monitor pain and pain management efficacy in children between ages 3 and 7 years.

Children below the age of 7 years usually cannot use the above scales. From ages 3 to 7 years, children can usually indicate their pain using one of a variety of "Faces" scales (Figure 100.4) [18]. Children below the age of 3–4 years cannot use such scales, and observational methods from nurses or family members may be used. The most commonly used, and best-validated, observational tool for preverbal children is the Faces, Legs, Activity, Cry, Consolability (FLACC) tool (Figure 100.5) [19]. Although designed specifically for assessment of postoperative pain, this tool has utility for preverbal children in other settings. In children with cognitive impairment, parental observation is a workable proxy measure [20]. A revised form of the FLACC is reliable and valid for cognitively impaired children [21].

Ability to function

The provision of adequate pain control is essential not only for humane reasons, but also to preserve the patient's ability to provide self-care and to maintain health. Function may be directly observed based on specific behaviors necessary to participate in HCT (bathing, exercise, and mouth care). Pain behaviors may be noted, such as requests for medication, grimacing, or refusals to move the affected area of the body [22].

Medication use and side effects

Analgesics reduce the sensation of pain and can improve function, but can also produce unacceptable side effects. The magnitude of drug consumption and the occurrence of common side effects should be monitored and recorded on the same scale format and on the same assessment sheets as pain scores.

Pain diagnostics and therapy selection

A clear diagnosis of the cause of a pain is essential in selecting therapies. To be effective, therapies must be aimed at the specific issues that contribute to the patient's problem. For pain with a large nociceptive contribution from tissue damage, for example OPM, antinociceptive agents (analgesics) are appropriate. For pain with a nociceptive component originating from neural tissue, different agents are appropriate, for example, anticonvulsants. For pain complaints that are concurrent with strong emotional/environmental components, treatments aimed at those components, in addition to pharmacologic agents, are appropriate. The first step in intervention is usually education as described below. Pharmacologic therapies should be pursued in a rational pharmacokinetic and pharmacodynamic fashion, for a period that will give the therapies a reasonable trial.

Treating the patient with difficult pain management problems

Pain may be alleviated by a variety of methods that can be initiated and used effectively by the staff caring for the patient. Sometimes, the magnitude of the problem may be beyond abilities of the primary caregivers. In these circumstances, the assistance of personnel with special expertise in pain management (nurses, neurologists, anesthesiologists, psychologists, and psychiatrists) may be helpful. The assistance can be provided in a variety of forms, ranging from occasional consultations to weekly "pain rounds," to the presence of a formal pain consultation team.

Non-pharmacologic techniques in pain management

When HCT patients report pain, analgesic medications are appropriately considered as a first line of treatment. Concurrently, non-pharmacologic methodologies are almost always incorporated into the treatment of the patient, whether or not these interventions are intended [23]. Even with optimal opioid and other analgesic methods, HCT patients with OPM may receive only 50–60% reductions in pain with analgesics [24,25].

Mechanisms of non-pharmacologic techniques

The broad goal of non-pharmacologic methods is to close the "gate" on pain messages, or to impede the transmission of pain messages and facilitate transmission of non-pain messages. In general, this is done by disrupting afferent pain pathways through the addition of competing sensory inputs, or by modifying descending pathways through changes in thoughts and responses to the sensory messages received.

A number of non-pharmacologic methods seem to operate mechanically, modulating transmission of ascending nociceptive messages by sending competing sensory messages from the body surface or limbs. Putting these mechanical methods into

Categories	Scoring		
	0	1	2
Face	No particular expression or smile	Occasional grimace or frown; withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs; frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to; distractable	Difficult to console or comfort
Each of the five categories is scored from 0–2, resulting in a total score between 0 and 10.			
The FLACC scale was developed by Sandra Merkel, MS, RN, Terri Voepel-Lewis, MS, RN, and Shobha Malviya, MD, at C.S. Mott Children's Hospital, University of Michigan Health System, Ann Arbor, MI.			

Figure 100.5 Assessment of Behavioral Score on the FLACC. Each category is scored 0–2 for a possible total of 10. 0, Relaxed and comfortable; 1–3, mild discomfort; 4–6, moderate pain; 7–10, severe discomfort/pain. Source: Merkel et al. 1997 [19]. Reproduced with permission of Pediatric Nursing.

operation requires activity. Patients must increase their physical activity, increase thoughts not focused on pain, and achieve an emotional calmness through a sense of control over some aspects of functioning. Lying in bed in a dark, quiet room, without outside stimuli, does not permit the activation of these mechanical methods and can lead patients to focus on the dominant sensory input – pain.

Staff and family members can assist patients by preparing structured activities and statements that facilitate attention to stimuli other than the pain. These need not be complex. Indeed, patients have limited attention span and often have disruptions in fine motor control. Simple conversation, walking outside the room or movement in the room, and simple games all serve to distract the mind from discomfort.

Education of patients and families, except in rare instances, provides reassurance and enhances the ability to cope with unfamiliar and uncomfortable situations. Autonomic nervous system activity decreases as anxieties and fears are allayed. Resultant changes in 5-HT and NE availability help patients as they prepare to guard against worsening symptoms. Adaptive thoughts are those that reassure or calm the patient and relax the autonomic nervous system.

Emotions are closely tied to and influenced by thoughts. Cognitive–behavioral methodologies for treating depression and anxiety successfully have been adapted specifically for cancer and HCT patients [23,25–28]. Patients who are more distressed pretransplant report greater pain during transplant [10,25]. Over time, unrelieved pain can engender feelings of helplessness and hopelessness. Introduction of alternative experiences of joy or self-control counters these feelings. When any of us feels more in control, we are better able to manage difficulties, and we feel less discomfort and less distress [9–11,29].

Strategies used in normal medical or nursing practice influence the thoughts that patients have about their situation. Information, education, and "reframing" techniques can facilitate coping. Other behaviors that are particularly useful in influencing both the ascending and descending modulatory systems include physical methods such as the use of ice or heat, rest when appropriate, transcutaneous nerve stimulation, and physical positioning (see [30] for details on the use of ice, heat, and massage).

Information

Information that can be helpful to patients includes:

1 Time-frame information. When is something likely to happen? How long will it last? It is helpful to break events into the smallest time frames possible.
2 Procedural information. What will be done? What comfort measures will be used?
3 Sensory information to prepare patients for specific discomforts.

Education

Education empowers patients to participate in their medical care and to modify their own behaviors. In addition to facts, patients must have the opportunity for dialogue to fit their own situation. Increasingly, patients and families administer their own pain medication and participate actively in medical treatment. To adhere to treatments, patients must understand them and not be frightened by the potential side effects.

The common barriers to willingness to use available pain treatments are well established [31,32]. Patients, family members, and medical staff frequently fear opioids and are reluctant to identify when treatment is inadequate. Specific areas where HCT patients and their families need education are listed in Table 100.2. Problems with resistance to medications or lack of understanding about pain are routinely prevented by conducting a brief assessment and education session with patients and families prior to the start of treatment. This session serves the additional purpose of identifying those patients who may experience difficulties achieving comfort.

Education alone can significantly reduce pain, reduce length of hospitalization, decrease complications, and improve overall

Table 100.2 Pain-related education need for hematopoietic cell transplantation (HCT) and their families

Question	Usual information offered
Why treat pain?	Pain is harmful to your physical health There is no benefit to proving you can stand pain without treatment, but there are serious negative health effects from suffering unnecessary pain
What treatments are common?	Most HCT patients need strong pain medications (opioids) at some time
When are treatments used:	
How often?	When pain is constant, scheduled doses provide better relief than waiting until pain is severe to take medication
How much at a time?	Your doctor will only prescribe safe levels of medication: let your nurse or doctor know if: You are too sleepy during the day Nausea increases when you take medication You have other symptoms that are new You have a new pain
How do you know when more is needed?	Pain medication should be used to keep pain under control, rather than waiting until pain is intolerable
Is addiction a concern?	HCT patients with no history of overusing drugs or alcohol have no cravings for the medication when the pain stops. Even people who need high doses of medication do not become addicts
Do people become tolerant to the drugs so that they stop working if pain gets really bad?	If you use the medication to keep the pain under control, the medication will not stop working when the pain increases, or if pain continues longer than expected
What if the medication does not work or makes a person sick?	There are many pain treatments. Tell your doctor or nurse if pain is out of control or if a medication makes you feel bad – numerous treatment options are available in these cases

outcomes [33–35]. Information and education do not cause anxiety where none exists, and they are not harmful [36,37].

Other cognitive–behavioral strategies

Reframing, active distraction, and relaxation are all techniques that can be valuable adjuncts to the use of analgesic medications. To the degree possible, speak about events in positive terms, give patients a sense of control (including participation in clinical decisions), involve patients in activities (if only as an observer at times), and provide a calm and caring environment. Research has shown that more specialized techniques, such as imagery and hypnosis, can be helpful but rarely eliminate the need for analgesic medications [25,27,38]. More widely available, and simple, techniques, such as progressive muscle relaxation, deep breathing, and concentrating on pleasant thoughts and places, also are helpful adjuncts to pain relief [39,40].

Pediatric considerations

Most of these methods need little adaptation for use with children. Age-appropriate information is important for children. As with adults, this information should reinforce areas over which the child has some control, such as asking for medication or understanding rewards for self-care activities. Children can plan for their own active distractions and can be engaged in play even when quite ill. Story telling, art projects, and play are effective imagery and distraction methods for children with pain.

It is crucially important to be aware that many children will withdraw from socializing when they are in pain. Their quiet demeanor should not be confused with comfort. Socialization and playfulness are often the best indicators of effective pain relief.

Non-opioid pharmacologic management of pain

NSAIDs and acetaminophen

Many non-opioid analgesics, both over-the-counter and prescription, are available. Two major groups are NSAIDs and phenacetin derivatives, acetaminophen being the only clinically used drug. All of these analgesics exhibit a "ceiling effect." Efficacy will increase with increasing doses up to a particular level; dosing beyond that point will not improve analgesia, but will expose the patient to dose-related side effects.

Other than the distinction that NSAIDs suppress inflammation and acetaminophen has few anti-inflammatory effects, there are few hard data on the comparable efficacy of the various agents as analgesics. Different agents offer varying durations of action, degree of side effects, and individual patient tolerance. These actions tend to be quite idiosyncratic, so it would be unwise to recommend any specific medication regimen. It is essential to tailor therapy on an individual basis.

Non-opioid analgesics are suitable for use in mild-to-moderate nociceptive and inflammatory pain. Alone they provide inadequate analgesia for moderate-to-severe nociceptive pain but, if used in conjunction with opioids, they may improve the quality of analgesia and demonstrate an "opioid-sparing effect," reducing the dose of opioid necessary to produce a given level of analgesia and thus reducing the potential for side effects. Non-opioid analgesics in the management of neuropathic pain currently are under study. Emerging data suggest a limited, but expanding, role for *N*-methyl-D-aspartate (NMDA) antagonists such as subanesthetic ketamine [41].

Pharmacology of NSAIDs and acetaminophen

The pharmacologic effect of NSAIDs is to inhibit the enzyme cyclooxygenase, part of the arachidonic acid cascade, reducing production of prostaglandins, one of the algogenic agents released by injured tissue (others being bradykinin, histamine, and 5-hydroxytryptamine) that stimulate or sensitize nociceptors. Consistent with their anti-inflammatory efficacy, the primary effect of NSAIDs classically has been believed to be peripheral. However, prostaglandins also play a role in the CNS transmission of pain [42–45]. Selective cyclooxygenase-2 (COX-2) inhibitors have limited antiplatelet activity and have less gastric toxicity than other NSAIDs, but are associated with an increased risk of major cardiovascular events [46]. (The only COX-2 inhibitor currently available in the United States is celecoxib.)

Acetaminophen produces similar analgesia to NSAIDs but, unlike NSAIDs, has only minor anti-inflammatory effects. Acetaminophen is as potent as aspirin in inhibiting prostaglandin synthesis in the CNS, but has little effect on prostaglandin metabolism peripherally [47–51]. Analgesic effects of acetaminophen and NSAIDs appear to be additive [52–54].

Side effects of NSAIDs and acetaminophen

Non-opioids have a variety of side effects that are of significance for, and limit their use in, the HCT patient:

1. Interference with platelet function. This lasts for days after stopping the drug in the case of aspirin, or for shorter periods with other NSAIDs. Although COX-2 inhibitors have little, or no, effect on platelet aggregation, they have recently been shown to increase the risk of cardiovascular events [46]. Acetaminophen has virtually no hematologic effects.
2. Gastric irritation and occult upper gastrointestinal bleeding. This is a feature of virtually all NSAIDs, to some extent, even the COX-2 inhibitors. Acetaminophen is benign to the gut.

3 Renal effects. In high dosage, NSAIDs have direct renal toxic effects. The effect of moderate NSAID dose upon already compromised renal function is not clear. Acetaminophen has virtually no renal effects.

4 Hepatic effects. In high dosage, acetaminophen is severely hepatotoxic, and it is generally recommended that patients not ingest more than 4 g daily, although the current thinking suggests that lowering the maximum daily dose to 3 g is safer [55]. The HCT patient may be at higher risk of acetaminophen toxicity due to the high incidence of concurrent or recent hepatotoxic therapy, graft-versus-host disease (GVHD), hepatitis, and poor nutritional status.

Use of NSAIDs and acetaminophen in HCT

The role of NSAIDs for pain management in the acute phase of HCT is limited by the fact that they are available only in oral form (except ketorolac), by their hematologic and gastrointestinal side effects, and by the fact that they may suppress pyrexia. The use of acetaminophen is limited primarily by its potential to suppress pyrexia. Table 100.3 includes dosing data for acetaminophen and the NSAIDs [56].

Table 100.3 Dosing data for acetaminophen and NSAIDs

Drug	Usual dose for adults and children >50 kg body weight	Usual dose for children[a] and adults[b] <50 kg body weight
Acetaminophen[c]	650 mg/4 h 975 mg/6 h	10–15 mg/kg/4 h 15–20 mg/kg/4 h (rectal)
Aspirin[d]	650 mg/4 h 975 mg/4 h	10–15 mg/kg/4 h 15–20 mg/kg/4 h (rectal)
Carboprofen	100 mg TID	
Choline magnesium trisalicylate[e]	1000–1500 mg TID	25 mg/kg TID
Choline salicylate[e]	870 mg/3–4 h	
Diflunisal[f]	500 mg/12 h	
Etodolac	200–400 mg/6–8 h	
Fenoprofen calcium	300–600 mg/6 h	
Ibuprofen	400–600 mg/6 h	10 mg/kg/6–8 h
Ketoprofen	25–60 mg/6–8 h	
Ketorolac tromethamine oral[g]	10 mg/4–6 h (to a maximum of 40 mg/day)	
Ketorolac tromethamine intravenous[g,h]	30 mg initially, then 15 mg/8 h	
Magnesium salicylate	650 mg/4 h	
Meclofenamate[i]	50–100 mg/6 h	
Naproxen	250–275 mg/6–8 h	5 mg/kg/8 h
Naproxen sodium	275 mg/6–8 h	
Sodium salicylate	325–650 mg/3–4	
Celecoxib[j]	200 mg/day	
Rofecoxib[j]	12.5–25 mg/day	

TID, three times daily.

[a] Only drugs that are approved by the US Food and Drug Administration as an analgesic for use in children are included.

[b] Acetaminophen and NSAID dosages for adults weighing less than 50 kg should be adjusted for weight.

[c] No antiplatelet activity.

[d] The standard against which other NSAIDs are compared. May inhibit platelet aggregation for more than 1 week and may cause bleeding. Aspirin is contraindicated in children with fever or other viral disease because of its association with Reye syndrome.

[e] May have minimal antiplatelet activity.

[f] Administration with antacids may decrease absorption.

[g] For short-term use (less than 5 days).

[h] Has the same gastrointestinal toxicities as oral NSAIDs.

[i] Coombs-positive autoimmune hemolytic anemia has been associated with prolonged use.

[j] Cyclooxygenase-2 inhibitors.

Source: adapted from Dahl and Raeder 2000 [52].

Antidepressants

TCAs have established their efficacy over decades and still are in widespread use. They have analgesic effects independent of their antidepressant effect, providing pain relief in the non-depressed patient, or providing pain relief, without affecting mood, in the depressed patient [57–59]. Moreover, the analgesic effects of many TCAs occur at lower dose and blood levels of drug than those which produce antidepressant effects. Newer selective serotonin reuptake inhibitors (SSRIs) are commonly used to treat depression, and they too may have analgesic effects.

TCAs are thought to relieve pain by altering the 5-HT and NE levels in the descending antinociceptive modulating system. Studies suggest that NE and 5-HT specificity are important in producing analgesia. In humans, concomitant 5-HT and NE enhancement is effective [60–62]. More recent work suggests that NE sites are more active; increased 5-HT levels have intrinsically weak analgesic effects but enhance the analgesic effects at NE sites [63–65].

Antidepressants for neuropathic pain

There is a growing literature on the use of antidepressants for neuropathic pain; see the section Neuropathic pain for details.

Antidepressant administration in HCT

There is concern about the use of TCAs in the HCT patient, as many TCAs appear to have marrow-suppressant effects [66]. Clinical experience indicates that up to 25% of HCT patients will have significant marrow suppression in the early engraftment period with TCAs. If TCAs are used, it is desirable to begin with a low dose, for example, amitriptyline 10 mg, and titrate upwards against side effects, which often are the limiting factors. It is helpful to have patients take the drug at bedtime so that sedation and other side effects are less problematic; better sleep may also lead to lower pain levels. All TCAs have long elimination half-lives. The analgesic effects of TCAs can occur within days or weeks, making it necessary to monitor clinical and hematologic function frequently.

Little is known about the clinical use of SSRIs in HCT patients, although this class of drugs is not normally associated with bone marrow suppression. The same can be said for the SNRIs.

Opioids in the management of pain

Drugs that produce analgesia by stimulating morphine-accepting CNS receptors are colloquially referred to as narcotic analgesics. It is more appropriate, however, to refer to these drugs as "opioids" rather than "narcotics." Semantically, the latter term associates the drugs with opium, the source of the prototype drug morphine. "Narcotic" is a legislative, administrative, or legal word, which is applied to a number of psychoactive drugs with abuse potential. In the current social and legislative atmosphere, the word "narcotic" should be avoided in medical settings.

The avoidance of the use of opioids by patients or healthcare professionals, in circumstances where they could be used safely and appropriately, is a grave disservice to those suffering from treatable pain. Opioids are not without liabilities, but the incidence and severity are often overstated. Pain relief is integral to humane treatment and, indeed, has been shown to attenuate disease in animals [67,68].

Opioid pharmacology

Opioids act at a number of different levels of the CNS to produce analgesia:

1 They inhibit the transmission of nociceptive input in the dorsal horn of the spinal cord (Figure 100.1).
2 They activate descending inhibitory systems in the basal ganglia (Figure 100.1) which modulate peripheral nociceptive input at the spinal cord level.
3 They affect the limbic system, altering the emotional response to pain, thereby making it more bearable.

Opioids bind primarily to μ and κ receptors in the CNS. Agonists, such as morphine, activate inhibitory pain pathways in both supraspinal and spinal regions. Antagonists, such as naloxone, competitively inhibit the analgesic effects of opioid agonists. Some opioid drugs exhibit both an antagonistic action (at μ receptors) and an agonist action (at κ receptors); these "mixed agonist–antagonists," such as nalbuphine and butorphanol, have clinical efficacy in HCT patients who experience a wide variety of gastrointestinal syndromes, especially those associated with cramping. Medications with mixed effects can precipitate an abstinence syndrome in people already taking opioid pain relievers, so must be used with vigilance.

Opioid pharmacokinetics

A schema of opioid pharmacokinetics with various modes of administration is given in Figure 100.6. As with many drugs, the blood levels of opioids that result can be measured and interpreted to yield a number of "half-lives." For individual patients, opioid pharmacokinetics and half-lives are fairly consistent. This is true to the extent that the blood levels resulting from a single dose of opioid may be used in sophisticated pharmacokinetic analyses to calculate infusion regimens that hold blood levels of opioid very close to a predetermined level [69]. However, opioid pharmacokinetics are highly variable from patient to patient, with half-lives and rates of elimination varying between two- and fourfold.

Opioid pharmacodynamics

Opioids exhibit dose-dependent effects in many realms of activity. The analgesic dose–response curve of opioids is not a straight line; they have a threshold of efficacy and a narrow "therapeutic window," and among individuals there is a wide range of effective analgesic blood levels of drug.

A useful concept is the minimum effective analgesic concentration (MEAC), the blood level of opioid at which a patient reports satisfactory pain relief (Figure 100.6) [70]. For an individual patient with a specific pain, the MEAC is fairly consistent. However, among individual patients with similar pains MEACs vary over a five- to sixfold range. For example, the mean MEAC of morphine is 16 ng/mL (range 6–33 ng/mL), and the mean MEAC of meperidine 455 ng/mL (range 94–754 ng/mL) [71].

The variability of individual MEACs, in conjunction with the individually variable drug half-lives and speeds of elimination, results in a wide range of opioid doses necessary to maintain analgesic blood levels. The practical manifestation is that opioid doses must be individualized, based on the effects of the drug, which in practice are derived from patient reports of pain relief and occurrence of side effects.

Opioid side effects

Opioids have a wide variety of side effects, many of which will abate or disappear with exposure over a several-day period.

Gastrointestinal effects

Opioids can induce nausea and vomiting in 10–40% of patients through several distinct mechanisms, including direct stimulation of the chemotactic trigger zone (CTZ), sensitization of the vestibular apparatus (patients with a history of motion sickness are especially vulnerable), and delayed gastric emptying [72]. Nausea and vomiting attributable to opioids usually occur at the onset of therapy or with escalation of dose. These symptoms, although common, often subside quickly with continued opioid exposure and may be relieved by changing opioid or using smaller doses of drug at more frequent intervals. The choice of antiemetic for symptom control should be tailored based on the presumed underlying mechanism of opioid induced nausea. Nausea and vomiting due to delayed gut motility (clinically presenting with postprandial nausea and vomiting or early satiety) may improve with promotility agents such as metoclopramide. Nausea and vomiting due to stimulation of the CTZ may be relieved with dopamine or 5-HT antagonists, and symptoms

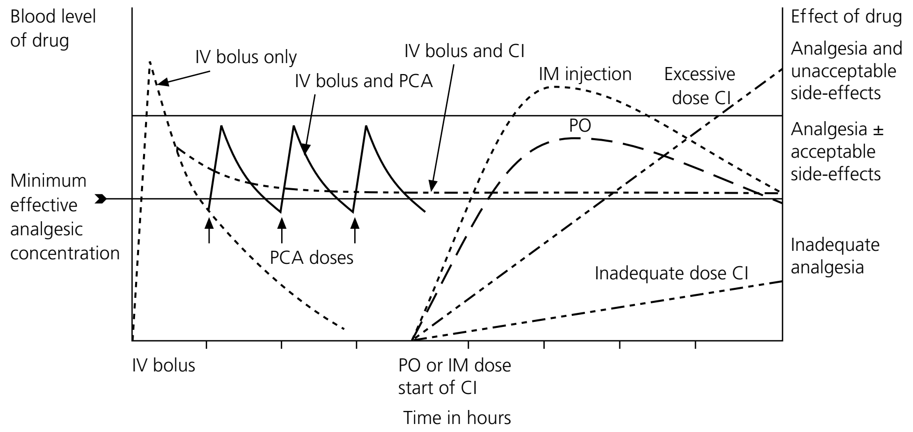

Figure 100.6 Pharmacokinetics of opioids with various routes of administration. The "therapeutic window" of opioids is the range of blood levels of opioid within which they produce satisfactory pain relief without unacceptable side effects. Following administration by various routes, plasma levels of opioids rise, according to the mode of administration, and then fall, depending on the speed of redistribution or elimination. As a general rule, as plasma levels of opioids rise they will reach the minimum effective analgesic concentration and enter the drug's therapeutic window. Rises in plasma level of drug beyond this therapeutic window produce some improvements in analgesia, but a large increase in the incidence and magnitude of opioid side effects. CI, continuous infusion; IM, intramuscular; IV, intravenous; PCA, patient-controlled analgesia; PO, oral.

exacerbated by movement may respond to diphenhydramine (a histamine-1 blocker) or scopolamine (an anticholinergic) [72].

Constipation, although a common side effect of opioids in general, is manifested differentially in the HCT patient due to the predilection for diarrhea from a variety of causes, including mucotoxic conditioning regimens, infections or GVHD. Prophylactic stool softeners and stimulants are therefore not routinely administered, and treatment is symptom based.

Genitourinary effects

Increased tone and contractility of the ureters and increased detrusor tone may lead to urinary retention.

Pruritus

Pruritus is a well documented yet poorly understood occasional side effect of opioid therapy. Antihistamines, rotation of opioids, and opioid dose reduction are common treatment strategies. In addition, mixed opioid agonists–antagonists, e.g. nalbuphine, can reverse itching, but this may also reduce the analgesic effects [72].

Sedation

Sedation is an almost universal side effect of opioids and usually occurs at onset of therapy or with dose escalation. Opioid-induced sedation typically resolves within 72 hours of initiating therapy. It is important to remember that the differential diagnosis of sedation in the HCT patient is broad and includes CNS-active drugs (antiemetics, anxiolytics, antihistamines, and calcineurin inhibitors), metabolic derangements (renal dysfunction and electrolyte disturbances), fatigue (sleep deprivation and disturbed biorhythms), and the prodrome of sepsis. In patients with persistent opioid-induced sedation, small doses of methylphenidate (5–10 mg two or three times per day), donepezil, or modafinil can ameliorate symptoms [73].

Euphoria

Opioid euphoria is rare in the HCT patient.

Dysphoria

If dysphoria occurs, it typically is early during opioid exposure and progressively declines with more prolonged exposure.

Delirium

Patients undergoing HCT can develop delirium (as defined by transiently impaired cognitive, emotional, or behavioral functions) for a variety of reasons. Because of this, a broad investigation into potential metabolic, infectious, and CNS etiologies should be undertaken. Opioids are potential contributors to delirium with the suggestion that opioid naïveté, comorbid illness, higher doses of therapy, and parenteral administration confer greater risk [73,74].

Cases of opioid-induced delirium that do not upset or scare the patient can be treated with reassurance alone. In the event of an agitated delirium, haloperidol or rotation of analgesic therapy to another opioid may be effective [75,76]. Reduction of the opioid dose by 25% can also improve symptoms [68]. However, it is important to note that, in other patient populations, poorly controlled pain confers a greater risk of delirium than the administration of appropriate parenteral opioids [77,78].

Respiratory depression

When monitored by sensitive indices, all opioids blunt the respiratory drive in a dose-dependent fashion. In the dose range that produces analgesia, respiratory depression (defined as an arterial partial pressure of carbon dioxide >5.6 kPa) is uncommon. Patients with pre-existing respiratory disease, those with sleep apnea-like symptoms, and those receiving other CNS-active drugs, especially benzodiazepines, are most at risk of respiratory depression. The degree of respiratory depression parallels the slowing respiratory rate and degree of sedation; these signs can be monitored if respiratory depression is a concern.

Opioid tolerance and dependence

Tolerance

Tolerance is the progressively decreasing effect (analgesic or other effects) of a given dose of drug when that dose is administered repetitively. Tolerance may be seen when a patient who has been achieving satisfactory analgesia with a given dose of drug progressively fails to achieve analgesia without evidence of an increase in nociception. If it occurs in the HCT patient, tolerance may be overcome by increasing the dose of drug or changing to a different opioid. Tolerance is a drug-related effect only and has little or no relation to addiction.

Incomplete cross-tolerance

When changing from one opioid to another, it often takes less than an equianalgesic dose of the second opioid (Table 100.4). This phenomenon is observed frequently, but the mechanisms are not completely understood. If there is a need to switch opioid medications, a good rule of thumb is to give approximately two-thirds of an equianalgesic dose and provide liberal amounts of breakthrough medication until a new equilibrium is established. Although most opioid-related side effects dissipate spontaneously after a few days, a change can provide analgesia at "lower" doses of the second drug, perhaps with fewer side effects.

Physical dependence

Physical dependence is characterized by the occurrence of an abstinence syndrome (yawning, lacrimation, sneezing, agitation, tremors, fever, tachycardia, and other signs of sympathetic arousal) if the opioid abruptly is withdrawn. Like tolerance, dependence is a drug characteristic, not a patient characteristic, and is a separate entity from addiction. Few patients who are opioid dependent are addicts (see below). Abstinence syndromes can be avoided by slow reduction of opioid dose (10–20% every day or every other day) or by using adrenergic α_2-agonists such as clonidine, which mask some of the peripheral adrenergic symptoms [56]. Using the strategies described below in the section on opioid tapering, it is rare to see a true abstinence syndrome when opioids are used with HCT patients.

Psychologic dependence (addiction)

This complication is characterized by an abnormal pattern of drug use; of drug craving for effects other than pain relief; by an overwhelming involvement with procuring and consuming the drug, even when such activity is contrary to the individual's best interests; and with a tendency to relapse into drug use after tapering off the drug. Addiction is the conjunction of genetic, psychologic, social, and cultural factors that affect an individual. Unlike tolerance and physical dependence, psychologic dependence is a patient issue, not a drug issue.

Until recently, practitioners believed that patients with no previous history of substance abuse who receive opioids therapeutically have an extremely low incidence of iatrogenic addiction, of the order of 1 in 2000–4000 [79], so that fear of psychologic dependence

Table 100.4 Dose equivalents and starting doses for opioid analgesics

Drug	Approximate equianalgesic dose (mg)		Usual starting dose			
			>50 kg		<50 kg	
	Oral	Parenteral	Oral	Parenteral	Oral	Parenteral
Morphine	30	10	30 mg/3–4 h	10 mg/3–4 h	0.3 mg/kg/3–4 h	0.1 mg/kg/3–4 h
Hydromorphone	7–15	1.5–3.5	6 mg/3–4 h	1.5 mg/3–4 h	0.06 mg/kg/3–4 h	0.015 mg/kg/3–4 h
Oxycodone	30	N/A	10 mg/3–4 h	N/A	0.2 mg/kg/3–4 h	N/A
Hydrocodone	30	N/A	10 mg/3–4 h	N/A	0.3 mg/kg/3–4 h	N/A
Methadone	10–20	10	10–20 mg/6–8 h	10 mg/6–8 h	0.1–0.2 mg/kg/6–8 h	0.1 mg/kg/6–8 h
Levorphanol	2	1	4 mg/6–8 h	2 mg/6–8 h	0.04 mg/kg/6–8 h	0.02 mg/kg/6–8 h
Meperidine	100	100	N/R	100 mg/2–3 h	N/R	0.75 mg/kg/2–3 h

in those patients should not be a concern. That has been called into question in the last several years and, in fact, most pain management practitioners now believe the risk of addiction not only is real, but is fairly high, particularly in patients receiving opioids for chronic pain, even in cancer patients [80].

Opioids commonly used in the HCT patient

Table 100.4 includes a list of opioids, their approximate equianalgesic doses, and dosage intervals for oral or intravenous use. The choice of agent should be limited to opioid agonists. The following are commonly used opioids in the HCT patient and some of their specific complications.

Morphine

The prototypical opioid agonist morphine can be given by any route but has low oral bioavailability (Table 100.4). Oral duration of effect is 3–5 hours, which can be extended to 6–12 hours by the use of sustained-release preparations. Morphine is conjugated in the liver to two major metabolites, 3-glucuronide and 6-glucuronide, which may produce unintended side effects (sedation and confusion). Glucuronidation is a high-capacity conjugative pathway in the liver, so morphine is relatively safe to use in patients with moderate degrees of hepatic failure. Since both glucuronides are excreted by the kidneys, morphine should be used cautiously in patients with any degree of renal impairment. On initial use, morphine has a 15–25% incidence of pruritus, or nausea and vomiting, which often diminish with use over a few days.

Meperidine (Demerol)

This opioid agonist has about one-tenth of the potency of morphine. Meperidine is metabolized to normeperidine, a renally excreted metabolite, which has pronounced excitatory and convulsive effects. In patients with normal renal function, normeperidine levels do not become problematic until relatively large doses of the parent drug have been administered over a prolonged period, for example, 800–900 mg/day over about 5–7 days. However, if used as an analgesic, this meperidine dose could be met or exceeded in the HCT patient. Therefore, patients with normal renal function should be restricted to short-term, low-dose use, for example, for chills and premedication before platelet transfusions. In patients with abnormal renal function, meperidine should be avoided, or its use greatly restricted.

Hydromorphone (Dilaudid)

This agonist has a range of effects similar to that of morphine. Hydromorphone is thought to be five to eight times more potent than morphine, although data from the HCT population support a dose equivalency of about 3 [56,81]. It is generally believed to have fewer side effects than morphine, but this belief is not substantiated by double-blind studies [82]. It is metabolized to a number of renally excreted metabolites, which appear to be pharmacologically inert, at least in clinically relevant doses. Hence hydromorphone is a good choice of opioid in patients with impaired renal function or those with unacceptable side effects with morphine.

Fentanyl

This is a classic agonist with a range of effects similar to that of morphine. It is 100 times more potent than morphine and has a faster onset of effect. In short-term use, it has a relatively short duration of effect, but in longer-term use, its duration of effect is similar to hydromorphone. Fentanyl is metabolized to a number of pharmacologically inert metabolites, and is a good choice of opioid in patients with impaired renal function or those with unacceptable side effects with morphine or hydromorphone. Fentanyl predominantly is administered intravenously. It is also available as an oral transmucosal product that is useful in some HCT patients. Transdermal fentanyl (Duragesic) is a useful alternative to intravenous opioids for patients needing long-term stable dosing, in the absence of fever, and with intact skin. It should be noted that the patch takes 16–24 hours to achieve stable plasma levels of drug, and conversely when the patch is removed, it takes 16–24 hours for plasma levels of drug to fall. Fentanyl patches are not recommended for treatment of acute pain in any patients and, even for chronic use, they may be problematic in HCT patients who may have skin problems or fluctuating body temperatures that make absorption unreliable and potentially dangerous.

Oxycodone

Available only in oral forms, both short- and long-acting, oxycodone has become a favorite (often in fixed combination with acetaminophen) in the treatment of both acute and chronic pain. Its potency is roughly 1.5 times that of oral morphine. It has a well-deserved reputation for being a drug with high abuse potential; chronic use, therefore, should be monitored carefully [83].

Butorphanol

This is a mixed agonist–antagonist with marked κ-agonist effect and moderate μ-antagonist effect. It is a useful drug for HCT patients in treating the pain from GVHD of the gut. Compared with μ-agonists, it is believed to impair visceral nociceptive transmission more and yet causes less gut stasis. Butorphanol may be given intravenously or by nasal inhalation. It is not recommended for moderate-to-severe pain syndromes because it has a relatively low analgesic ceiling and can precipitate abstinence syndrome if the patient is on other opioids [56].

Nalbuphine

This is another mixed κ-agonist–μ-antagonist opioid. It effectively treats opioid-induced pruritus without reversing analgesia. Additionally, clinical experience has demonstrated efficacy in treating pruritus associated with cholestasis [84,85].

Tramadol

This is a centrally acting synthetic analgesic. It has weak opioid activity and inhibits reuptake of both 5-HT and NE. The side-effect profile is similar to that of opioids; respiratory depression may occur with overdose, and an abstinence syndrome can occur with abrupt withdrawal.

Buprenorphine/naloxone (Suboxone)

Buprenorphine alone is a μ-agonist and κ-antagonist that has been used in the treatment of chronic pain because it has a "ceiling" effect, both for analgesia and, more importantly, for respiratory depression. Naloxone, of course, is a powerful μ-antagonist used primarily in the emergency treatment of opioid overdose. The combination of the two drugs, Suboxone, is now a common treatment for chronic pain in patients with a history of opioid abuse. Its use in acute pain management for the opioid-naïve patient is contraindicated and it presents great challenges, due to the μ-antagonist effects, in the management of pain in a patient already on the drug. Discussion of its use in the HCT patient is beyond the scope of this chapter; if a patient who is on Suboxone presents for treatment, it is mandatory to have a pain management specialist involved.

Opioid use in clinical practice

The basic precept in providing analgesia with opioids is to raise and maintain the patient's plasma level of opioid above the patient's MEAC and within the therapeutic window. Figure 100.6 will help with understanding the following paragraphs.

Oral administration

The gut readily absorbs opioids but they undergo extensive first-pass metabolism by the liver, so that to produce a given blood level, the oral dose may be three to six times the parenteral dose (Table 100.4). After oral administration, blood levels rise slowly, reach the effective range in 30–45 minutes, and remain within the therapeutic window for about 3–4 hours; hence 3–4-hourly dosing is necessary, except with methadone, which is effective taken every 6–8 hours. Slow-release preparations of morphine and oxycodone extend this dosing schedule to 8–12 hours.

Rectal administration

This route should be avoided in the HCT patient because of the bacterial shower produced by inserting a suppository.

Intramuscular and subcutaneous opioids

Intramuscular and subcutaneous opioids are rarely used in the HCT population as frequent doses may be necessary, and the mixture of intramuscular/subcutaneous injections and thrombocytopenia results in hematoma formation.

Intravenous bolus

Intravenous bolus dosing rapidly raises the plasma level of a drug. However, the drug is then rapidly redistributed and metabolized, and blood levels fall quickly. Consequently, therapeutic levels, above the MEAC, are maintained for only a short period, less than 30 minutes. Intravenous bolus administration is widely used in the HCT population as most patients have indwelling venous access. The drug reliably and rapidly reaches its targets.

Fixed-rate (continuous) infusion

Infusions of opioid take a long time to raise plasma levels to the effective range, leaving the patient in pain. Moreover, to choose an infusion rate that will maintain an effective plasma level of opioid, the rate at which the individual patient metabolizes and excretes the opioid must be known. Chosen infusion rates can be excessive, leading to plasma levels of drug rising into the toxic range, or inadequate, leading to plasma levels falling into the poor analgesia range (Figure 100.6).

Intravenous bolus followed by a fixed-rate infusion

An intravenous bolus will rapidly raise plasma levels of drug to therapeutic levels that then can be sustained with continuous infusion. Patient report will determine the initial effective bolus (loading) dose. An hourly infusion rate equal to approximately 20% of the effective loading dose usually provides good relief. Intensive nurse monitoring is necessary to guarantee relief and avoid overdose.

Patient-controlled analgesia

In the early 1970s, the revolutionary concept that patients might be capable of acting as their own "sensor" of pain relief and analgesic need was advanced. The concept held that if patients were given as-needed access to opioids, they would titrate their dose to keep plasma concentrations at analgesic levels, close to the MEAC, thereby achieving satisfactory analgesia, and would not over- or underuse the opioid, even when the drug was taken over long periods. This concept reached clinical reality with the advent of computerized pumps that enable patients to self-administer small doses of opioids at frequent intervals, the clinical technique of patient-controlled analgesia (PCA).

The plasma levels of drug, which result from a loading dose plus PCA, are shown in Figure 100.6. By individualizing the dosage of opioid, allowing the patient to titrate to analgesic effect, PCA circumvents the problems posed by other modes of administration, that is, variations in MEAC, pharmacokinetic differences, and changes in degree of nociception. Virtually all adult patients have the cognitive and discriminative ability to use PCA. PCA can be used reliably by children down to at least the age of 12 years [86], and may even be safely and successfully used in some children down to the age of 4 or 5 years [87]. Current clinical practice is to offer PCA to younger children, provided they are able to grasp the concept and use the technique. If a child can play a video game, he or she probably can use PCA.

In HCT patients, the classical instance of PCA use is for mucositis pain. As the mucositis pain becomes worse, patients use more drug, and then, as their mouth and throat heal and the pain lessens, they naturally taper their opioid dose (Figure 100.7). In randomized controlled clinical trials, testing patients with PCA versus continuous infusions of opioid for mucositis pain, patients using PCA tend to have lower pain scores and use less drug over shorter periods, and hence a tendency to have fewer side effects [88]. PCA pumps have various parameters that must be defined for safe and effective use. When used effectively, PCA can decrease nursing time, provide more timely pain relief, and involve the patient importantly in symptom relief.

PCA bolus dose

Initial recommended bolus sizes are morphine 0.5–2 mg (10–30 μg/kg) in adults and 10–20 μg/kg in children, or equivalent doses of other drugs. As nociception and pain worsen, bolus size should be increased; if nociception and pain become less, dose size should be decreased. Experience has shown that the optimal bolus size is one that permits the patient's 24-hour drug need, obtained from the nursing records or the PCA pump memory, delivered in 25–40 doses.

PCA lock-out interval

After a bolus of opioid has been delivered, the pump will not deliver another dose for this set interval, usually 6–10 minutes. This is a safety feature as it prevents the administration of a further dose of drug until after the patient has had the opportunity to experience the effects (analgesia and sedation) of the previous dose.

PCA plus fixed infusion

PCA alone has some disadvantages. If a patient sleeps or is disconnected from the intravenous infusion and does not self-administer opioid, blood levels of the drug will fall. The patient may then have difficulty in self-administering sufficient drug to raise the blood level of opioid back into the analgesic range. To circumvent this problem, PCA pumps have a constant infusion option. This option should not be used until a patient has established their individual dose requirement, that is, by opioid use via PCA alone. For example, a patient may have used 84 mg of morphine in the previous 24 hours. This averages 3.5 mg of morphine per hour. It is advised that the infusion be set at not greater than 30–50% of the expected opioid need with some day–night variability as needed – in this case 1.0–1.8 mg/hour. In addition to helping with sleep, the addition of an infusion means that the blood levels of opioid fall more slowly after each PCA dose, giving the patient a longer period between the need for repeat PCA doses.

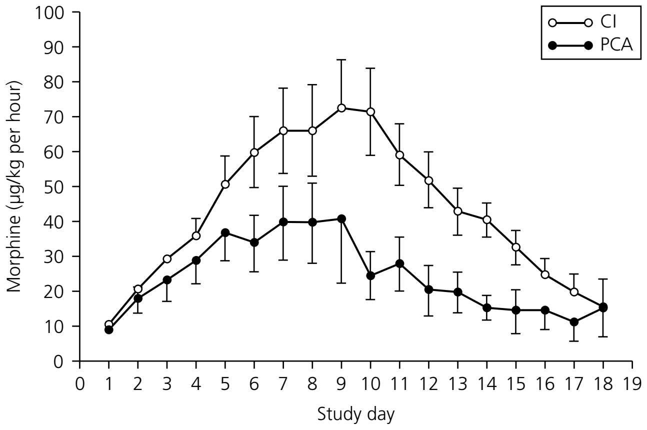

Figure 100.7 Daily mean morphine dose for adolescents with mucositis pain during hematopoietic cell transplantation. Morphine was delivered by physician-prescribed continuous infusion (CI) or patient-controlled analgesia (PCA). As the pain worsened, the PCA patients delivered more drug, and as the mucositis healed, they automatically tapered their dosage. Note also the lesser amount of drug used by the PCA patients, even though the pain scores were very similar in the two groups. Results were the same in adults [22]. Source: Mackie et al. 1991 [86]. Reproduced with permission of Elsevier.

Studies in postoperative patients using PCA for 24–48 hours have not shown a marked improvement in analgesia or patient satisfaction by the addition of an infusion to PCA [89,90]. Nonetheless, there is a strong body of opinion that the addition of an infusion to a PCA improves the quality of analgesia in HCT patients when pain persists over days, and can help with sleep.

Opioid tapering

Some HCT patients have pain problems of extended duration, which necessitate opioid therapy for long periods. Usually, as the pain problem diminishes, a patient's PCA or oral self-administered opioid dose is gradually reduced and ultimately eliminated. However, with relatively long-term (10–14 days) use, a patient may be physically dependent on the opioid; that is, abrupt cessation of opioid intake may precipitate an abstinence syndrome. In the HCT patient, these symptoms can be confused with stress reactions or can be attributed to infections or symptoms of GVHD.

It is important that both physician and patient understand that these symptoms are entirely unrelated to addiction (see the sections on physical dependence and psychologic dependence) [56], and that even if an abstinence syndrome does occur, it is rarely physically dangerous and does not have sinister long-term implications, although it is very unpleasant. The onset of these symptoms can occur within 6–12 hours after an opioid dose reduction, and peak at 24–72 hours. For both humanitarian reasons and treatment success, any tapering process should be designed to minimize the possibility of an abstinence syndrome; and if an abstinence syndrome occurs, it should be treated by using small doses of opioid until the symptoms dissipate.

Practical realities of tapering

All patients should be watched closely for abstinence symptoms since they may not be aware that their experiences are related to changes in opioid dose. If an abstinence syndrome does occur, an intravenous infusion or PCA dosing schedule that eliminates symptoms is the first intervention. This dose is then reduced by about 10–20% per day, assuming that the pain or abstinence syndrome does not reappear [91].

For ambulatory patients, continuous monitoring for symptoms by medical staff is not possible, and therefore a slower taper is advised. One simple method is the "pill count." The patient is prescribed the usual opioid in a tablet preparation, and is instructed to take it on a time-contingent basis (consistent with the duration of effect of the opioid) rather than as needed. Reductions of 10–20% of the dose are successively made until the patient is taking no drug. Immediate-release opioid preparations usually provide greater dosing flexibility than do sustained-release preparations which cannot be divided. Peripheral adrenergic symptoms during the taper can be avoided or masked by using adrenergic α_2-agonists such as clonidine [56].

For more complex patients, such as those who are overly focused on the dose or number of tablets, an alternative to the pill count method is to use "pain cocktail" [91,92]. In this strategy, the patient's mean daily intake of opioid is combined into a fixed volume of a taste-masked liquid vehicle, for example, cherry syrup, and the volume is split into regularly scheduled doses appropriate to the expected duration of action of the drug. When reducing the opioid content, the total daily volume stays stable, but the milligram opioid content is reduced by 10–20%.

Clinical pain management in the HCT patient

Pre transplant

Approaching and entering a transplantation program is an exceedingly stressful experience for patients, and may result in more vulnerability than usual to a variety of stresses, including pain. This is also a time of peak motivation to understand and participate actively in anything that will improve treatment comfort or success. Patients and families should be assured that symptom management, including pain, will be treated effectively, safely, and in a timely manner. In particular, education about the appropriate and safe use of opioids in HCT is important so that fears of addiction may be dispelled prior to the need for these medications. The pre-transplant period is the ideal time to learn, practice, and perfect non-pharmacologic pain-relieving skills.

As the time of the transplant comes closer, analgesic drugs that may be contraindicated during the transplant, for example TCAs, SSRIs, and NSAIDs, should be stopped, and safer substitutes, for example, opioids or shorter-acting anxiolytics such as clonazepam, begun.

In-hospital, peri-transplant period

This is the most vulnerable time for the patient. Pain management measures used are those least likely to impede engraftment or to interfere with the patient's ability to function. Analgesic drugs are usually given intravenously, as patients are frequently unable to take oral medication, and intramuscular injections are contraindicated.

It is more difficult to evaluate and treat patients who use non-prescription psychoactive drugs. In these individuals, who may likely be opioid tolerant, analgesic use is usually greater than normal, and the clinician evaluating the success of therapy may have to rely on external observable criteria rather than the usual patient report criteria. Contracts may need to be set to outline explicit behaviors that must be adhered to by the patient, to ensure that drug delivery is maintained or increased. Expected behaviors can include all the self-care activities necessary, along with appropriate interactions with staff in relation to anger control, manipulations, inappropriate drug-seeking activities, and number of requests for medications. When the nociceptive phase of the transplant is over, it may be necessary to impose an externally derived, relatively rigid opioid tapering schedule, rather than allowing the patient to self-taper as is normally done.

Pseudoaddiction

Care must be taken not to underdose patients who have previous, licit or illicit, experience with opioids, or who simply have high opioid requirements due to idiosyncrasies associated with the drugs. Persistent underdosing of patients leaves them in pain, and often sets up an undesirable cycle in which the patient continually asks for medication and the staff, frustrated, begin to deny medication or label the patient as a "drug-seeker." These behaviors can lead to accusations of addiction when, in fact, it is the failure to provide adequate pain relief that is at fault.

Patients with prior history of substance abuse

Patients who have a history of substance abuse (tobacco, alcohol, illicit drugs, opioids, or sedatives) may present management problems in the peri-transplant period, especially with opioid tapering. It is essential to identify these at-risk patients prior to transplant, provide adequate analgesia (see pseudoaddiction above), set clear guidelines for acceptable behavior, and be cognizant of increased opioid requirements. Opioid withdrawal may be made easier by providing time-contingent medications, rather than "as-needed" dosing, removing a layer of control from the patient.

The following are the most common pain problems and their management approaches.

Oropharyngeal mucositis

The conditioning regimens and GVHD prophylaxis used in HCT can result in OPM requiring systemic opioid analgesia in 60–100% of patients [10,93,94]. Onset of oropharyngeal discomfort typically occurs 5–7 days after the initiation of chemoradiotherapy, and peaks at day 9–13 of HCT. Resolution of symptoms usually occurs 3–4 weeks after transplantation and parallels neutrophil recovery. The duration of analgesic need may range from a few days to several weeks. Biologic predictors of mucositis-related pain correlate with the degree of tissue damage and include type and intensity of chemoradiotherapy, the use of methotrexate for GVHD prophylaxis, age, clinical grade of mucositis, and source of stem cells. Psychosocial predictors of mucositis pain have also been identified and include pre-transplant HCT-related distress, type of pain-coping strategy employed, depression, and solitary living status [10,95].

Recent approaches to combat mucositis have focused on prevention. There is a growing experience with reduced-intensity or alternative conditioning regimens that are less mucotoxic. In addition, alternatives to standard methotrexate for GVHD prophylaxis are under investigation. A systematic review found convincing evidence that ice chips, amifostine, hydrolytic enzymes, antibiotic paste, calcium phosphate rinses, and good oral care protocols are effective in reducing the severity of mucositis [96]. Keratinocyte growth factors have been shown to be safe and to decrease the duration of mucositis pain in the autologous transplant setting [97]. Studies are ongoing to assess the safety and efficacy of this class of agents in the allogeneic setting.

Once OPM pain has been established, topical analgesics such as viscous lidocaine and benzydamine can offer effective pain control [96,98]. These agents should be swished and expectorated several times daily, and are often used in conjunction with mucosal coating agents such as diphenhydramine. As the severity of OPM increases, these topical agents become inadequate, and systemic opioids are often required.

Oral opioids are of limited use owing to the high frequency of concurrent odynophagia, nausea/vomiting, and poor gastrointestinal absorption. The systemic management of mucositis pain is therefore usually accomplished with parenteral opioids. When frequent intravenous doses are required, the use of PCA is appropriate in adults and children who can manage it. In patients who cannot manage PCA, continuous infusion plus bolus dosing when needed is often required. Specifics on PCA use for mucositis pain are described above in the sections Opioid use in clinical practice and Opioid tapering.

Despite current preventive strategies and systemic opioid therapy, many patients still report ongoing mucositis pain [95]. Psychologic techniques (such as relaxation and cognitive–behavioral training) may be helpful in conjunction with systemic opioids [10]. Further investigations into preventive and non-opioid alternative pain management strategies are needed.

Conditioning regimen-related cutaneous skin toxicity

In HCT, this complication occurs predominantly in the hands, feet, groin, axillae, and genitalia. The magnitude of skin disruption varies from mild erythema to frank lesions similar to second-degree burns which usually heal 6–10 days postengraftment. The skin lesions may require treatment with silver-containing creams or biologic dressings such as pig skin. For mild toxicity, cold packs often supply adequate pain control. For more severe pain, opioids, as used for OPM, are appropriate.

Hepatic capsule distention

Sinusoidal obstructive syndrome (SOS) of the liver may cause liver engorgement with capsular distention. Intravenous or PCA opioids as for OPM are appropriate. Patients with SOS will tolerate and metabolize opioids normally until either the SOS becomes severe (bilirubin ≥20 mg/dL), hepatic failure ensues, or renal dysfunction occurs. It is essential to remember that the high-capacity hepatic degradation pathways may overwhelm a mildly dysfunctional kidney leading to accumulation of degradation products, particularly important with meperidine and morphine.

Pain associated with hematopoietic growth factors

The recombinant granulocyte colony-stimulating factor filgrastim is commonly used to hasten neutrophil recovery and to mobilize donor stem cells. Headaches and bone pain (usually in the pelvic and long bones) are frequently reported and are dose dependent. Bone pain can occur within hours of filgrastim administration and usually resolves within a few days of drug cessation. Pain is typically well controlled with acetaminophen or NSAIDs, although low-dose oral opioids are occasionally required. In published series, between 60 and 100% of donors undergoing stem-cell mobilization with filgrastim report bone pain severe enough to require some type of analgesia. Although rare, bone pain can occasionally be severe enough that hospitalization is required [99]. A growing experience with the longer-acting pegfilgrastim shows comparable incidences of bone pain [100,101]. Outpatients receiving filgrastim or pegfilgrastim should have access to ample “as-needed” doses of a rapid-onset oral opioid such as morphine, hydromorphone, oxycodone, or hydrocodone, often in combination with acetaminophen. Of interest, loratidine is being explored as a safe alternative to treat pegfilgrastim induced pain [102].

Postengraftment

Graft-versus-host-disease

Patients who receive allogeneic transplants are at risk for GVHD, despite prophylaxis with immunosuppressive drugs and steroids. The following are commonly occurring sites of GVHD that tend to have accompanying pain:

1. *Oral.* Oral GVHD can overlap with the signs and symptoms of OPM. Symptom-based treatment includes good oral hygiene, topical analgesics, and oral or systemic opioids titrated to effect.
2. *Skin.* The pain of skin GVHD responds to opioids. Skin GVHD also associated with pruritis can be effectively treated with oral hydroxyzine or nalbuphine, as pruritus may be mediated through systems that are opioid sensitive [84,103]. The TCA doxepin can be fairly effective in treating itch from any cause.
3. *Gastrointestinal tract.* Gut GVHD may cause pain for a variety of reasons. Bowel wall inflammation may cause pain at rest and with movement. Vigorous peristalsis of inflamed gut may cause episodic cramping pain that is not responsive to opioids. Indeed, opioids may make the pain worse by contributing to bowel dysmotility. Clinical experience strongly suggests that κ-agonist opioids such as butorphanol produce better pain relief and less gut atony than μ-agonist opioids. There may be a place for the use of invasive analgesic techniques such as epidural analgesia, which provide potent analgesia with low-dose drug use, in this circumstance. Chronic GVHD is a difficult pain management problem, and long-term opioids or one of the invasive analgesic techniques should be considered.

In circumstances in which opioids are not very helpful, and pain is unpredictable and brief, as in chronic GVHD gut cramping, patients can use an image that counteracts the physical sensation, combined with deep breathing. For example, a patient with a cramping pain might imagine a tight fist that progressively relaxes as they blow out each slow, deep breath. Or, in the case of burning pain, the patient might imagine breathing arctic air through the hot body part, and watching as the red turns to orange and cools to green or blue. Both adults and children have used this method to shorten the duration of pain.

Pain associated with steroid tapering

This usually occurs at the time when steroids are being tapered slowly. Typically, the pain is severe, of rapid onset and short duration, and usually occurs in the distal femur and proximal tibia in the early morning hours. Usually this pain is responsive to opioids – but doses need to be large enough to abort the pain episode.

Pain due to herpes zoster

The acute episode is painful in about 75% of cases. Pain may persist beyond the acute episode. Pain that persists beyond 1 month may be due to peripheral nerve damage and is therefore termed postherpetic neuralgia (PHN). In the acute episode, non-opioid agents and opioid analgesics are appropriate and effective. For PHN, non-opioid and opioid analgesics are relatively ineffectual. With PHN, three types of pain, which respond to differing therapeutic modalities, occur:

1. Severe skin sensitivity with pain to the slightest touch (allodynia). Eutectic Mixture of Local Anesthetics (EMLA cream, a 2.4% lidocaine–2.5% prilocaine mixture applied topically) or more recent preparations such as lidocaine patches might be considered [104]. Effective systemic drugs include anticonvulsants and antidepressants (see the section Neuropathic pain below).
2. Episodic shooting pain best thought of as an epileptiform discharge from damaged dorsal horn neurons (see the section Neuropathic pain below).
3. A background burning pain, which is the most common form of PHN. This often responds well to TCAs [61,62] and occasionally to opioids.

Prevention of PHN has been the subject of various studies. The early suggestion that corticosteroids might prevent PHN [105] has not been confirmed [106]. More recent studies strongly suggest that early use of antiviral medications may reduce the incidence and duration of PHN [107,108]. Even more exciting is gathering evidence that early sympathetic blockade (e.g. by using epidural analgesia) shortens the acute phase and reduces the incidence, duration, and severity of PHN [109,110]; combined with antiviral therapy, this would now appear to be the intervention of choice, especially in patients over 50 years old.

Neuropathic pain

Damage to nerves may cause neuropathic pain. Such pain typically is out of proportion to the stimulus intensity; it can involve myelinated Aδ nerve fibers or smaller, unmyelinated C fibers. Damage to the latter in particular may cause "sympathetically mediated" pain syndromes. These syndromes may be amenable to neural blockade, whereas non-sympathetically mediated pain syndromes usually are not.

Neuropathic pain often is associated with sensory or autonomic nervous system dysfunction. Patients tend to use words such as "burning," "raw," "gnawing," "aching," or "tightness" to describe the discomfort of neuropathic conditions. Shooting and shock-like pain syndromes also can occur. Common causes include exposure to chemotherapeutic agents (particularly vinca alkaloids), calcineurin inhibitors, damage to large neural plexi by radiation or surgery, spinal cord compression, or nerve root infiltration in conditions such as herpes zoster. The incidence of neuropathic pain in HCT patients is unknown. Mechanisms of the various syndromes are still poorly understood; consequently, there are many treatment options, and it is difficult to predict efficacy. In the last few years, however, coherent approaches to the management of neuropathic pain have emerged, based on our current understanding of NE and 5-HT neurochemistry [63,65,111]. See the following two sections.

Antidepressants for neuropathic pain

Many HCT patients suffer from neuropathic pain. Even though there have been no clinical trials of TCA or SSRI analgesic efficacy in HCT patients, it probably is reasonable to extrapolate to the HCT population data from trials in other conditions, usually diabetic neuropathy or PHN models [112].

TCAs have been shown to be variably effective in some patients. Compared with placebo, amitriptyline, imipramine, and desipramine produce benefits in neuropathic pain when administered in either low or high dose [58,60,62,113,114]. Benefits appear after about 2 weeks; a frank correlation between blood level of drug and analgesic efficacy has not been established. Amitriptyline is probably the drug of choice, but desipramine is a good alternative with similar efficacy and possibly fewer side effects [61,62].

Although it has been difficult to show that SSRIs have clear analgesic efficacy in neuropathic pain syndromes, there is emerging evidence that they may be beneficial, in particular that SSRIs may enhance analgesia from TCAs [63,64]. An even newer antidepressant, duloxetine, which is a 5-HT and NE reuptake inhibitor, is less well studied but also shows promise in refractory neuropathic pain syndromes [115,116]. There is a growing consensus that SNRIs are effective in treating neuropathic pain in non-HCT patients [117] and these strategies may legitimately be extrapolated to HCT patients.

Anticonvulsants for neuropathic pain

A wide variety of anticonvulsants, including carbamazepine, phenytoin, valproic acid, and clonazepam, have been used to treat neuropathic pain, with some success [112,118]. The more recently developed anticonvulsants gabapentin and pregabalin, however, appear to be more effective, safer, and better tolerated by cancer patients, especially in those patients at risk for developing PHN [117,119–124].

Topical preparations for neuropathic pain

Topical application of lidocaine patches [125,126] and capsaicin [127,128] has been used successfully to control peripheral neuropathic pain. Topical capsaicin has been used to treat mucocutaneous neuropathic pain, such as oral mucositis [129], although it is recommended only for early or mild cases because capsaicin can cause severe pain by releasing substance P.

Opioid treatment of neuropathic pain

The historical dogma that opioids are ineffective in treatment of neuropathic pain has been shown to be false [130–132]. Neuropathic pain does, indeed, respond to opioid treatment, but may require higher doses than in the treatment of nociceptive pain. Further, adjunctive treatments may enhance and complement analgesia provided by opioids in the setting of neuropathic cancer pain [133,134]. It is often helpful to treat neuropathic pain with opioids until the effect plateaus or unacceptable side effects emerge. As noted above in the section on addiction, long-term opioid treatment may incur risks of psychologic dependence and abuse.

Pain due to diagnostic or therapeutic maneuvers

Postlumbar puncture headache

Postlumbar puncture headache (PLPHA) is believed to be caused by a continuing leak of cerebrospinal fluid through the hole in the dura created by the lumbar puncture. This leak may cause a low-pressure headache or traction on the base of brain structures as they migrate distally through the foramen magnum. Additionally, there likely is a reflex vasodilation is response to the abnormal hydrostatic pressure gradient across the brain [135]. Lumbar punctures should be performed with the smallest needle possible, certainly no larger than 22 G, and preferably 25 G. With a 22 G needle, the incidence of PLPHA is 20–30% in 20–30-year-olds but only 2–3% in those over 60 years old.

A classic PLPHA is an occiput to frontal headache that occurs after a lumbar puncture and that is exquisitely sensitive to positional changes. It may be associated with photophobia, nausea, vomiting, tinnitus, diplopia, and changes in auditory and visual acuity. Not all headaches postlumbar puncture are PLPHAs. Patients with a history of headaches are more likely to get one after lumbar puncture, but whether these are PLPHAs is often debatable.

Prophylactic measures that minimize the incidence of PLPHA include:

- Using small needles, preferably those with non-cutting "pencil point" tips, such as Whitacre or Sprotte needles.
- Single punctures.
- Lying flat after the lumbar puncture, presumably allowing the dural hole to heal. A 1-hour initial period followed by as much time as possible recumbent for 24 hours is advised. This has never been shown to be true evidentially but is, nevertheless, advised by experts.

Once a headache has occurred, a variety of treatments can be used:

- Bed rest, mild analgesics, and copious fluids.
- Caffeine infusion, 500 mg in 500–1000 mL over 1–2 hours repeated twice, if needed, barring side effects such as tachycardia or uncontrolled anxiety.
- Wearing an abdominal binder while out of bed. This increases intra-abdominal pressure, increases epidural blood flow, and reduces transdural pressure gradients, thus reducing cerebrospinal fluid loss.
- Epidural blood patch. This is performed by doing an epidural puncture at the site of the lumbar puncture, and then instilling 10–15 mL of the patient's own blood into the epidural space at the

site of the previous puncture. The blood either decreases the transdural pressure gradient, allowing the hole to heal, or acts as "physiologic glue," sealing the hole. Epidural blood patches should be used with caution in the HCT patient because of the risk of creating an epidural hematoma in the coagulation-impaired patient, and of introducing a perfect bacterial culture medium close to the neuraxis in an immunocompromised patient.

- Use of triptans. Anecdotal evidence and clinical experience indicate that the migraine-aborting medication sumatriptan, available orally and as a nasal spray, and also applied by the intramuscular route, is useful in the treatment of PLPHAs and may obviate the need for blood patching.

Surgical pain

HCT patients often undergo a number of procedures, ranging from the simple, with little postoperative pain, for example indwelling central line placement, to the complex and painful, for example lung biopsy. The management of postoperative pain in HCT patients should be aggressive. Invasive techniques, such as epidural catheters for administration of spinal opioids and local anesthetics, should be weighed carefully. After thoracic and abdominal surgery, epidural analgesia can aid pulmonary function and overall activity; there is a small risk of infection at the catheter site [136,137]. A complicating feature of postoperative pain management in HCT is that many patients will be opioid tolerant. In such cases, it is recommended to replace presurgical opioids completely with a basal infusion of drug and provide liberal breakthrough dosing either by PCA or frequent nurse-delivered boluses, depending upon the cognitive function of the patient. Even though opioids do not have true logarithmic dose–response curves, they behave as if they do in patients who are tolerant. Hence it is not surprising that many patients will require, at least, double their previous daily opioid requirements in the acute postoperative phase. Self-titration via PCA allows the patient to escalate and subsequently wean medication to acceptable levels of comfort with minimal risk of respiratory depression.

Analgesia/sedation for painful and unpleasant procedures

HCT patients have to undergo a number of different painful, unpleasant, and anxiety-provoking procedures. In small children, the only way in which these can be accomplished is under deep sedation or general anesthesia. Preprocedural fears and intraprocedural discomforts can be managed in a variety of ways, as described below.

Non-pharmacologic management of procedures

Cognitive–behavioral and physical methods can be effective for both preprocedural anxiety and active distraction during procedures [138]. These methods require patients to be alert; even moderate sedation with benzodiazepines disrupts the effectiveness of these methods. Relaxation and imagery can effect cognitive distraction and reduce physical stress.

Pharmacologic management of procedures

Pharmacologic management can take a variety of forms, depending on the procedure, the patient, and local resources. Adults often will tolerate procedures with local anesthetic and a minimum of CNS-active drug. Children are likely to need more CNS-active drugs. In increasing order of complexity and invasiveness, the following techniques can be used.

Cutaneous local anesthetic

A 1-hour cutaneous application of EMLA will produce dense skin anesthesia. Infiltration of skin and deep structures with percutaneous local anesthetic is highly efficacious. Local anesthetics do not work instantaneously, and it is good practice to leave the local in place for about 5 minutes before attempting any potentially painful maneuver. The addition of 2–3 mL of standard sterile sodium bicarbonate solution to a 30 mL vial of 1% lidocaine will reduce or eliminate the stinging pain of injection.

Premedication

Small doses of an anxiolytic (e.g. midazolam) and a short-acting opioid (e.g. fentanyl) prior to the procedure will make injection of local anesthetic more pleasant for patients. Patients often will have no recollection of the procedure, but will recall the experience less unpleasantly even when there were difficulties or the patient expressed discomfort.

Conscious sedation

Conscious sedation is achieved with opioids and sedatives, given in doses higher than those used simply for premedication, such that patients remain responsive to verbal stimuli and are able to protect their airway and breathe spontaneously. Only qualified nurses and physicians should provide conscious sedation due to the potential need, albeit small, for airway support.

One approach is the use of lorazepam plus an opioid such as morphine or hydromorphone, medications that patients often are on already. The strategy is to "top off" the existing sedative and analgesic for the procedure with the knowledge that respiratory compromise would be extraordinarily rare because patients will previously have developed respiratory tolerance to those drugs. Another common combination of drugs is midazolam plus an opioid; this is less safe since the respiratory-depressant effects of midazolam are more pronounced and unpredictable than with lorazepam, and because patients rarely are on midazolam chronically so will not have built up a respiratory tolerance to the medication. In either case, it is important to weigh the risks of aspiration against the benefits of providing deeper sedation than would be achieved with premedication alone, if, for example, the patient has severe mucositis.

Deep sedation and general anesthesia

The continuum from conscious sedation to deep sedation, when the patient is virtually unarousable, to general anesthesia, when the patient is rendered unconscious, is indistinct. Whereas well-trained nurses can administer conscious sedation safely, only those providers who are highly skilled in airway management and interventions for cardiovascular instability should provide deep sedation and general anesthesia. Such regimens typically consist of a short-acting, potent opioid plus an intravenous anesthetic; fentanyl (short-acting due to rapid redistribution) and remifentanil (which degrades spontaneously in the plasma) plus propofol are two commonly used methods. The authors discourage the use of ketamine, another alternative, because it is longer acting, creates copious secretions, and often is associated with postadministration delirium. The American Society of Pediatrics has provided practice guidelines for such situations [139].

Invasive analgesic techniques in the HCT patient

In the non-HCT population, patients whose longer-term nociceptive pain is poorly managed by systemic analgesics are candidates for one of a number of potent, but invasive, analgesic techniques. In HCT patients, these techniques have been used infrequently owing to the risks of hematoma and infection. Post-HCT, there are patients with severe pain problems that are not responsive to systemic analgesics, for example, chronic gut GVHD or pathologic fractures, who should be considered for these potent techniques. Examples of the techniques, their potential indications in the HCT patient, and potential complications are as follows:

1. Peripheral nerve blocks with local anesthetic for pain in well-circumscribed anatomic distributions. For example, intercostal blocks may be appropriate for fractured ribs, chest tube placement, or following thoracotomy.
2. Sympathetic nerve blocks with local anesthetic in conditions that have a sympathetic nervous system-mediated component. For example, stellate ganglion blocks may be appropriate for head and neck herpes zoster.
3. Neurodestructive sympathetic nerve blocks for pain that is likely to be longstanding and resistant to other analgesics. For example, neurodestructive celiac plexus block may sometimes be considered for pain associated with intra-abdominal candidiasis.
4. Neuraxial (epidural or subarachnoid) blocks with either opioids or local anesthetic. The techniques may be used on a short-term basis, for example, for postoperative pain after thoracic or abdominal surgery, via percutaneously inserted catheters. For pain of likely longer duration, such as gut GVHD, more complex and expensive implanted systems may be considered.
5. Spinal cord stimulation is a highly specialized technique that utilizes electricity to modulate efferent and afferent pain signals in the central nervous system. Clinical data have demonstrated varying degrees of efficacy and, in all cases, careful patient selection is paramount.

Analgesia and sedation in dying patients

In providing pharmacologic relief of discomfort in dying patients, the choice of the most effective and least burdensome route of drug delivery is often a problem. Choosing the route of drug administration in the HCT patient is simplified by the fact that most people have indwelling central venous catheters. The fundamental drug in providing comfort care is an opioid. The choice of opioid may be suggested by what has been used effectively earlier in the patient's course.

Both continuous infusion of opioids and PCA have a role to play, although, as the patient's condition deteriorates, they will less likely be able to use PCA effectively. If patients are not receiving any opioid, one should start with either PCA or continuous infusion as for mucositis, and adjust doses upwards based on response. If patients are receiving opioids, doses should be adjusted upwards to achieve comfort. It is often necessary to use high doses of opioid to obtain comfort, and the usual dose increases may be inadequate. In these circumstances, a bolus dose of 1 hour's worth of opioid, followed by an increase of 25–50%, may be necessary. The occurrence of unwanted side effects, such as nausea, delirium, agitation, tremulousness, or other CNS phenomena, can be treated by changing to an equianalgesic dose of another opioid or by the addition of further CNS-active drugs, including low-dose (0.5–1.0 mg/kg) ketamine once or twice per day [140].

In the event that opioids do not provide adequate comfort, especially if there is poor control of anxiety or tremulousness, sedative drugs such as benzodiazepines or barbiturates should be considered. Initial benzodiazepine regimes would be midazolam 1–2 mg/hour and lorazepam 1–2 mg/hour; dose increases of 25–50% are appropriate. As with opioids, substantial doses may be needed. Another useful category of drug is the butyrophenones, such as haloperidol and droperidol. These can be used to treat delirium and confusion, and, in association with opioids, they may produce a calm, neuroleptic-like state. Sample regimens would be haloperidol 0.25–1.0 mg/kg or droperidol 0.1–0.2 mg, intravenously every 4–6 hours.

In the terminal stages, agitation may require the use of potent CNS depressants such as barbiturates (pentobarbital 1–2 mg/kg bolus, and continuous infusion 1–5 mg/kg/hour or phenobarbital 200 mg IV/SC bolus, then CII/CSI at 600 mg/day; usual maintenance dose, 600–1600 mg/day) or propofol (50–200 µg/kg/min) to provide "palliative sedation" [141,142]. In some instances, comfort measures can shorten a patient's life. The Rule of Double Effect (also called the Doctrine of Double Effect), which invokes the axiom that intervening on the patient's behalf may incur risks, including the possibility of death, is a well-accepted ethical principle; it protects the practitioner legally and permits extreme comfort measures in dying patients. The Rule of Double Effect derives from Catholic moral theology and has roots as far back as Thomas Aquinas [143]. A full discussion of end-of-life ethics is beyond the scope of this chapter; ethical principles are fundamental but often do not account for the complex sociology surrounding death and dying [144].

Conclusion

This chapter has outlined the neurophysiology and pharmacology of pain, and has described the common sources of discomfort in patients undergoing HCT. It provides practical guidelines for the evaluation and pharmacologic treatment of pain in HCT. Most HCT patients can be managed effectively by the oncology team. In situations where continued inadequate or ineffective analgesia prevails, it is strongly recommended that a multidisciplinary expert pain relief team be consulted and involved.

CHAPTER 101

Oral Complications of Hematopoietic Cell Transplantation

Mark M. Schubert[1], **Maria Elvira Pizzigatti Correa**[2] **and Douglas E. Peterson**[3]

[3] School of Dental Medicine and Neag Comprehensive Cancer Center and UConn Health Center, Farmington, CT, Seattle, WA, USA

Introduction

Oral complications can present a wide range of lesions and changes for hematopoietic cell transplantation (HCT) patients ranging from mild transient complications to chronic disabling lesions to life-threatening disease. Lesions can arise from pre-existing dental or other oral diseases or can arise from HCT treatment specifics (e.g. conditioning regimens) or HCT-associated complications [e.g. graft-versus-host disease (GVHD)]. The importance and impact of comprehensive supportive oral care for HCT patients are recognized as an integral component of HCT patient management. Comprehensive HCT oral supportive care can reduce patient suffering, the risk for medical complications, and healthcare resource utilization and also improve the long-term outcome of transplantation. A multidisciplinary team approach to incorporating HCT oral care protocols can result in optimal oral and systemic management. Evidenced-based management guidelines continue to be developed and can be utilized to provide direct benefits to the patient's overall clinical course.

Correlations with the phases of transplantation

Oral complications occur in all phases of transplantation (Table 101.1) and generally reflect the patient's oral health status as influenced by the patient's overall status, including pre-existing dental health problems, HCT-associated adverse sequelae, and their associated management.

Risk factors for oral complications include, but are not limited to, underlying systemic and oral disease, patient age, type of donor, HCT conditioning regimen, post-HCT immune status, and availability of supportive care. For example, the risk for chronic oral complications (e.g., GVHD, salivary hypofunction) is considerably elevated in allogeneic recipients compared with autologous HCT recipients [1]. The ability to recognize patterns for oral complications can help with the diagnosis and management of oral complications since many of the varied oral lesions and infections can have a non-specific presentation.

Pre-transplantation oral evaluation and stabilization

The primary goal of pre-HCT oral evaluation and care is to identify and eliminate pre-existing oral and dental disease that could contribute significantly to oral complications post-HCT [2–5]. All oral lesions should be assessed and diagnosed, including those that involve the dentition, periodontium, maxilla and mandible, mucosa, and salivary glands. Causes of these lesions could include infection, drug reactions (including bone-modifying agents), or neoplasia. Clinical examinations should be augmented by radiographic imaging and appropriate tests. Microbiology and virology testing for lesions and/or special tissue tests including tissue biopsy may be indicated.

Patients should be informed about potential oral complications of HCT and should be educated about standard oral care protocols. Transplant candidates should be advised to seek complete oral and dental evaluations and treatment as early possible prior to presenting for transplant. The dental team needs to be involved with the pre-HCT oral evaluation whenever possible; it is imperative, however, that the dental care providers clearly understand the goals and objectives of pre-HCT stabilization and provide appropriate and realistic care. To maximize ideal oral management, the oncology team should advise the dentist and hygienist as to the patient's medical status, timing of treatment, and expected course post-HCT recovery. Dental care should be targeted at eliminating or stabilizing oral and dental diseases that could complicate HCT recovery. It should be recognized that routine dental care will need to be postponed until immunologic recovery has occurred post-HCT – this can vary from 6 months post- HCT for autologous patients to as long as several years for allogeneic HCT patients with chronic GVHD (cGVHD). For patients whose medical condition prohibits dental treatment, medically necessary non-invasive oral care should be provided until routine dental care can be performed.

Dental treatment

Any medically necessitated pre-HCT dental treatment ideally should not interfere with the planned start of transplant conditioning or induce situations that could increase the risk of complications (e.g. non-healed dental extraction sites). The level and complexity of care and the time required to complete pre-HCT need to be balanced by the medical, financial, and emotional considerations relative to the patient's situation.

Table 101.1 Phases of hematopoietic cell transplantation in relation to oral complications and management

Transplant phase	Time interval	Oral complications	Highlights of oral management
Phase I	Prior to conditioning	Pre-existing oral/dental disease – Dental caries – Endodontic infections – Periodontal disease: gingivitis, periodontitis – Oral mucosal infections: viral, fungal, bacterial Oral complications of recent cancer therapy Oral manifestations of malignancy – Gingival leukemic infiltrates – Oral lymphoma TMD	• Pre-HCT dental examination and radiographs • Elimination of dental, periodontal, endodontic, and oral mucosal lesions/infections • Patient education relative to oral complications and their management
Phase II	Initiation of conditioning therapy through trilineage engraftment	Acute conditioning regimen toxicities – Oropharyngeal mucositis – Oral infections – Xerostomia – Taste Dysfunction Mucosal infections: viral, fungal, bacterial Periodontal/dental infections Oral hemorrhage Acute GVHD (allogeneic transplants) GVHD prophylaxis toxicity (methotrexate)	• Maintain routine oral hygiene measures • Mucositis prevention and symptom control protocols • Infection surveillance and treatment as indicated – Viral (HSV, CMV) – Fungal (*Candida*, molds) – Bacterial • Local hemorrhage control • Management of xerostomia symptoms • Topical/symptomatic therapy for oral aGVHD • sTMD management
Phase III	Trilineage marrow engraftment to normal circulating counts	Persistent conditioning regimen toxicities – Xerostomia – Taste dysfunction Oral mucosal infections – Fungal (*Candida*, molds) – Viral (HSV, CMV) – Bacterial[a] Oral aGVHD (allogeneic transplants) – Mucosal lesions – Xerostomia Neurotoxicity (tremors, numbness, pain, taste dysfunction) Dental hypersensitivity TMD	• Maintain basic oral hygiene • Symptomatic management of xerostomia, including dental caries prevention • Infection surveillance and treatment as indicated • Surveillance for/diagnosis of oral aGVHD
Phase IV	Normal hematologic counts to immunologic recovery	Chronic toxicities of conditioning regimens – Xerostomia – Taste dysfunction Oral manifestations of GVHD – Resolving acute GVHD – Emerging chronic GVHD Oral mucosal infections – Oral candidiasis – Viral infections (VZV, HPV, HSV) – Bacterial infections[b]	• Maintain basic oral hygiene • Management of xerostomia including dental caries prevention • Surveillance for/diagnosis of oral GVHD with treatment as indicated • Infection surveillance/ treatment of infections • Resume routine dental examinations (4–6 months post-HCT) – Avoid elective and less than urgent treatments – Emergency dental care with medical support/ avoid elective dental treatment
Phase V	Long-term survival: full functional immunologic recovery	Chronic toxicities of conditioning regimens – Xerostomia – Taste dysfunction Oral manifestations of cGVHD Oral mucosal infections – Oral candidiasis – Viral infections (HPV, VZV, HSV) – Bacterial infections[b] Second malignancies post-transplant – Lymphoproliferative disorders – Squamous cell carcinoma – Salivary gland tumors Craniofacial growth and development abnormalities in children	• Maintain basic oral hygiene • Management of xerostomia, including dental caries prevention • Surveillance for/diagnosis of oral GVHD with treatment as indicated • Infection surveillance and treatment • Surveillance for potential second malignancies post-transplant

CMV, cytomegalovirus; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; HPV, human papillomavirus; HSV, herpes simplex virus; TMD, temporomandibular dysfunction; VZV, varicella-zoster virus.

[a] Mucosal bacterial infections during this phase become increasingly uncommon unless engraftment is slow or if the patient has aGVHD or is on GVHD therapy.

[b] Mucosal bacterial infections are rare unless the patient has severe cGVHD, especially when on intensive therapy for GVHD.

Dental caries and endodontic infections

Dental caries and endodontic infections are common dental problems requiring stabilization prior to transplantation [5,6]. Dental caries treatment may need to be prioritized: more extensive caries is at higher risk for causing systemic infectious complications post-HCT, and therefore a high priority for pre-HCT stabilization. Less urgent decay can be managed conservatively or even deferred until it is medically appropriate to resume routine dental care post-HCT.

If a pulpal infection occurs post-HCT, the resulting endodontic infection can be difficult to manage and can even be life threatening. Therefore, endodontically infected teeth should be treated prior to HCT with either endodontic therapy or extraction.

Periapical radiolucencies associated with endodontically treated teeth should be carefully evaluated. Radiographic changes associated with endodontically treated teeth can result from a number of factors, including infection, inflammatory reactions, apical fibrous scars, cysts, and even malignant lesions [2]. In cases where periapical radiolucency is associated with an endodontically treated tooth and there are no signs or symptoms of infection, retreatment or extraction is not typically needed since the radiolucency is most likely due to an apical scar [2]. However, if risk exists for infection or treatment failure after transplantation for these teeth, retreatment or extraction should be performed.

Periodontal disease stabilization

Infectious periodontal diseases (gingivitis and periodontitis) pose the most frequent and significant infectious disease risks for patients post-HCT [7]. Periodontal disease in patients pre-transplantation can range from mild marginal gingivitis to severe chronic periodontitis with deep periodontal pocketing, bone loss, and chronic abscesses. In diseased sites, the tissues lining the periodontal pockets are infected and ulcerated and at risk for causing local, regional, and systemic infection, with also an increased risk for bleeding. Gingival bleeding predominantly results from pre-existing periodontal disease and is not due solely to low platelet counts. Healthy gingival tissue does not typically bleed unless traumatized. Patients should not be instructed to stop routine brushing and flossing "because their platelets are low" – rather, it is important to continue with appropriately administered oral hygiene as described below, in order to prevent infection and reduce the risk for gingival bleeding.

The single most important consideration for controlling periodontal infections is effective and consistent tooth brushing and flossing – effective dental bacterial plaque removal can render mild-to-moderate gingival/periodontal infections at "low risk" for spread of infection. More severe disease often requires additional antimicrobial therapy (topical, systemic, or both) and subgingival periodontal treatment (root planing and curettage). Periodontal disease-stabilizing procedures need to be completed prior to myeloablation; patients then need to maintain excellent oral hygiene [1]. However, teeth with severe periodontal involvement (i.e. significant bone loss, often accompanied by mobility) should be extracted. In situations where extractions are not feasible owing to medical status, subgingival time-release minocycline can be placed in diseased periodontal pockets around day 0; this strategy can reduce bacterial colonization for 3–4 weeks and thus reduce the risk for periodontally related infection risks during the period of most profound neutropenia.

Debate exists as to the management of unerupted or partially erupted third molars ("wisdom teeth") prior to transplantation. Some authors recommend extraction of all fully impacted or partially erupted third molars prior to HCT. However, many authors favor a more conservative approach that endorses extraction of third molars only if the teeth have a history of acute periodontal infections (pericoronitis) during the previous 12–18 months and/or if gingival health cannot be maintained with routine oral hygiene measures.

Dental extractions

When dental extractions are indicated, they should be performed as atraumatically as possible, with primary closure if feasible. It is difficult to define a minimal time for healing of extraction sites before initiating conditioning, but the more time that can be afforded for healing after surgery before myelosuppression post-HCT, the better. Epithelialization of the extraction sites can reduce the risk for local infection, bacteremia, distant infection, and bleeding [8]. The amount of time necessary for initial healing generally increases when infection is present (periodontal and/or endodontic infections), or with surgical extractions. For example, a simple extraction with primary closure of a non-infected tooth will generally initially epithelialize in 14 days. In contrast, extraction of multiple adjacent teeth or an impacted mandibular third molar can require as long as 21–28 days to heal adequately. The healing of extraction sites for patients previously treated with bisphosphonates is often delayed and can take upwards of 4–6 weeks (see below).

Dentures and orthodontic appliances

Removable prostheses (e.g., full or partial dentures, occlusal guards, etc.) should be examined thoroughly and adjusted as needed prior to HCT. Poorly fitting appliances can traumatize oral mucosa compromised by cytotoxic chemotherapy or radiation and can increase the risk for mucosal ulceration, thus increasing the risk for pain and infection. During HCT conditioning and for the first several weeks post-HCT, dentures should be worn minimally (e.g. only during eating) to reduce the risk of mucosal injury and secondary infection. Antimicrobial soaking solutions are strongly recommended when dentures are being stored, and soaking solutions should be changed daily [1].

Orthodontic bands and fixed appliances, with the exception of fixed lingual retainers, should be removed prior to conditioning to reduce the risk for mucosal trauma. Additionally, metal dental restorative materials and orthodontic appliances produce radiation backscatter with total body irradiation (TBI) that can increase radiation damage for tissues overlying the metal surfaces [9]. Large metallic dental restorations or metal orthodontic appliances can be covered with 3–4 mm thick vinyl mouth guards during radiation treatment to hold tissues away from the metal surfaces and reduce radiation damage. The use of removable orthodontic retainers can be discontinued for the first 3–4 weeks post-HCT and then use can be resumed. If orthodontic bands and brackets cannot be removed, custom vinyl mouth guards should be utilized to help reduce mucosal trauma.

Temporomandibular dysfunction

It is important to identify patients with a history of temporomandibular dysfunction (TMD), especially those presenting with a myofascial pain component. Parafunctional habits (cheek or lip chewing, clenching, and/or bruxism) should be identified, and efforts should be considered to reduce these behaviors. Sleep dysfunction and emotional stress can acutely increase parafunctional clenching/bruxing habits. Physical therapy modalities (moist heat/cold packs, massage and muscle stretching for muscles, and cold packs for painful joints) can help control symptoms. Muscle relaxants can be useful for managing acute muscle-based signs and symptoms of TMD. Efforts to improve sleep and reduce stress will often help to resolve myalgia and headache pain.

Prophylactic antibiotics

The need for prophylactic antibiotics prior to any dental procedures escalates as the risk for bacteremia and infection increases for immunosuppressed patients. However, there are no evidence-based guidelines for the use of prophylactic antibiotics for dental treatment prior to and following HCT. Prudent clinical practice suggests that prophylactic antimicrobials may well be of benefit for patients with low neutrophil counts ($<1000/mm^3$) or who are otherwise immunocompromised. Some authors have recommended antibiotic prophylaxis prior to dental procedures to reduce bacteremia and potential colonization of central venous access catheters by oral bacteria. This recommendation is empiric and based on anecdotal experience but not evidence-based analysis [10,11]. The policy endorsed by the authors established in collaboration with the input from infectious disease consultants recommends the following:

1 Patients at increased risk of infection due to poor immune status (e.g. neutrophils $<1000/\text{mm}^3$) should receive appropriate antibiotics prior to dental treatment and, as the risk of infection increases, the intensity of antibiotic supportive therapy needs to be increased.
2 Until further evidence is available, patients who have central venous access catheters in place should receive antibiotics to prevent colonization of the catheter following dental treatment-induced bacteremia, using the American Heart Association's prophylactic antibiotics guidelines for patients at high risk for infectious endocarditis. Standard prophylactic antibiotics for specific medical situations (e.g. endocarditis risk, dialysis catheters) should be used.

Post-HCT oral complications

Post-HCT, oral complications generally have distinct patterns of occurrence and reflect parallel systemic HCT toxicities and pathologies (Table 101.1). Early post-HCT oral complications primarily arise from the direct toxicities of conditioning regimens or indirectly from systemic toxicities and immune status. These complications can involve only the oral cavity or may represent oral manifestations of systemic involvement. Specific oral complications can occur acutely (days 0–100 post-HCT), possibly becoming chronic, or initially arise later post-HCT. Distinct patterns of oral complications are recognized with specifics of HCT (e.g. autologous/syngeneic versus allogeneic HCTs or myeloablative versus reduced-intensity conditioning regimens). The recognition of the risk factors for oral complications and their clinical patterns can significantly improve the diagnosis and management of HCT oral complications.

Acute direct conditioning regimen toxicities are dominated by oropharyngeal mucositis, salivary gland dysfunction, and taste dysfunction. Acute indirect toxicities are generally related to infectious complications, thrombocytopenia, or acute GVHD (aGVHD). Chronic oral complications are generally related to chronic toxicities of conditioning regimens and cGVHD and include infections, xerostomia, oral cGVHD lesions, second malignancies post-HCT, and compromised dental and craniofacial growth in children.

Oral care protocols

Standard HCT oral care protocols are designed to maintain oral health and prevent infectious and bleeding complications. These protocols can be subclassified into (1) oral hygiene protocols to prevent infection due to dental/periodontal disease and (2) strategies to maintain mucosal stability and oral comfort [5] (Table 101.2).

Oral hygiene

There can be significant benefits of maintaining oral health, especially periodontal health. Bacterial dental plaque accumulation causes infection and can progress to regional infection and bacteremia [12,13]. Maintaining gingival health by reducing oral bacterial plaque accumulation can reduce the risk of bacteremia and gingival bleeding. Basic components of oral hygiene protocols are tooth brushing and flossing. Tooth brushing and flossing represent the most appropriate and cost-effective approach to dental plaque control relative to the prevention of gingivitis and periodontal disease. Oral care protocols that mandate that patients discontinue brushing/flossing when blood counts (notably platelets) decrease below defined thresholds are mistakenly based on the concept that these oral hygiene activities cause undue risk of bleeding. Consistent plaque control promotes gingival health, decreases exacerbation of oral mucositis due to oral microbial colonization, and reduces risk of bacteremia and bleeding in myelosuppressed transplant patients [3].

Table 101.2 Routine oral hygiene and mucosal care

Tooth brushing
Soft/ultrasoft nylon-bristle brush
Electric/ultrasonic toothbrushes with soft bristles are acceptable
Brush twice per day with the Bass sulcular scrub method
Rinse frequently with water or normal saline
– Toothpaste as tolerated – discontinue use if causes pain (consider using non-mint flavors)
– Frequent rinsing with 0.9% saline solution or water if not using toothpaste
Brush with 1.1% sodium fluoride when there is increased risk of dental caries (salivary gland dysfunction, inadequate oral hygiene)
Foam tooth brushes: not recommended
– Use *only* when impossible to use a regular soft nylon toothbrush
– Use *with* antimicrobial rinses (e.g. chlorhexidine) when possible
– Resume use of a nylon-bristled toothbrush when possible
Flossing
Floss once daily with an atraumatic technique
Interproximal brushes: use once daily as instructed
Bland oral rinses
Types of rinse
– 0.9% saline solution (three-quarters of a teaspoon of NaCl in 32 oz of water)
– Sodium bicarbonate solution (2 tablespoons of sodium bicarbonate in 32 oz of water)
– 0.9% saline/sodium bicarbonate solution (three-quarters of a teaspoon of NaCl + 2 tablespoons of sodium bicarbonate in 32 oz of water)
Total volume of 12–16 oz rinsed, held mouthful by mouthful, and expectorated
Repeat every 1–4 hours or as required for pain/irritation
Topical fluorides
1.1% neutral sodium fluoride gel (preferred)
0.4% stannous fluoride gel
Brush on for 3–5 minutes, expectorated, and rinse as directed. Apply once per day
Topical antimicrobial rinses
0.12–0.20% chlorhexidine oral rinse
Minocycline or doxycycline rinse (100 mg/4 oz water)
Rinse, hold for 1–2 minutes and expectorated. Repeat 2–4 times per day

Tooth brushing

Daily removal of bacterial dental plaque from teeth and gingival tissues is critical for maintaining oral health [3,5]. Patients should be given instructions and trained in proper brushing technique prior to HCT; their ability to comply with correct brushing technique should be reviewed on a regular basis throughout HCT recovery. Patients should brush with a soft or extra-soft nylon-bristled toothbrush twice per day using a standard sulcular brushing technique. If toothpaste causes burning or stinging, it can be discontinued and water or saline solution rinsing substituted until mucositis resolves. Vigorous oral rinsing with water or saline solution while brushing will aid in removal of bacteria and debris dislodged by the brushing. Brushes should be air dried between uses. Electric/ultrasonic toothbrushes can be used if patients are properly trained in their use. If it becomes necessary to suspend the use of standard tooth brushing, it should be resumed as soon as possible after oral mucosal lesions improve.

Foam toothbrushes are not effective in removing dental plaque and do not promote gingival health. Furthermore, foam brushes can abrade mucosal surfaces and can potentially promote mucosal breakdown when patients are at risk for mucositis. The use of foam brushes in conjunction with a topical antimicrobial solution has been reported to be more effective than the use of only foam brushes but still is not equal to standard brushing.

Dental flossing

The removal of bacterial plaque interdentally is critical for maintaining gingival health. If patients demonstrate correct dental flossing techniques, they should continue flossing throughout HCT recovery. Patients with fixed lingual retainers have to floss involved teeth; if they are unable to or unwilling to commit to the effort required to floss these teeth, the retainer should be removed and can be replaced once the patient has been able to resume routine dental care. Although interproximal brushes can help with removing debris from inter proximal areas, they are not a substitute for flossing.

Antimicrobial rinses

Topical antimicrobial agents can aid in the control of bacterial colonization of gingival tissues. Chlorhexidine oral rinses are the most commonly available product for this purpose. Other potentially antimicrobial rinses include tetracycline, minocycline, doxycycline, and povidone iodine [3]. Antimicrobial rinses should be utilized when patients are unable to perform standard brushing and flossing.

Topical fluorides and remineralizing products

Patients with active dental decay or at increased risk for dental caries, especially those patients with xerostomia, should use topical daily fluoride therapy and/or remineralizing therapy. Neutral 1.1% sodium fluoride gel can be applied with a brush-on technique (Table 101.2).

Oral mucosal care

Oral mucosal care protocols should be utilized on a daily basis [1]. Bland oral rinses not only promote patient comfort, but also help maintain hydration of the oral mucosa and thus reduce risk of secondary infection.

Oral mucosal protection protocols are based on non-medicated care strategies that emphasize frequent rinsing with bland rinses (e.g. saline solution, sodium bicarbonate or saline–sodium bicarbonate solutions) (Table 101.2). These approaches are directed at keeping mucosal surfaces moist, neutralizing acidity, eliminating thick mucus secretions, and soothing mild-to-moderate mucosal discomfort. Some patients prefer to use "iced" bland rinses where ice chips are added to the basic solutions immediately prior to use. These solutions do not typically need to be sterile and can be prepared as needed.

Hydrogen peroxide rinses should not be used as a routine mouth rinse because of their tendency to dry tissues and interfere with wound healing. However, a mixture of 3% hydrogen peroxide and 0.9% saline solution (1:1 to 1:3 by volume) can aid in removal of blood clots or mucous accumulations. Lemon glycerin swabs also should not be used as glycerin can cause mucosal dryness. Commercial mouthwashes are not generally recommended because they can cause stinging/burning and increase mucosal dryness.

HCT patients should be encouraged to minimize potential trauma and irritation to oral mucosa. Avoiding rough textured foods/vigorous chewing, stopping parafunctional habits (e.g. lip–cheek chewing habits), and careful oral hygiene can reduce the risk of mucosal injury and breakdown.

Medicated care strategies are utilized to manage specific oral lesions. Examples include the use of topical antibiotics for "neutropenic ulcerations," treatment of candidiasis with antifungal agents, and topical steroids for aphthous ulcerations. Diagnosis of oral lesions is critical in order to deliver appropriately targeted interventions.

Patient education

Patient education and compliance with care protocols are an important element of the oral care plan. In addition to oral hygiene care instructions, patients must be educated as to potential oral complications of HCT, such as mucositis, oral bleeding, oral infections, GVHD, and pain. Patient motivation is key to acceptance of responsibility for their self-care protocols, and they should understand that their efforts can have a positive impact on their clinical course. Individual patient needs must be addressed in developing oral care regimens [14].

Oropharyngeal mucositis (OM)

Oral mucositis is a frequent, serious toxicity of phase II of HCT therapy [14,15]. Approximately 80% of patients who receive high-dose conditioning regimens prior to HCT develop clinically significant OM [1]. For patients receiving myeloablative conditioning regimens, OM has been reported to be the single most debilitating complication of a transplant, causing severe pain and affecting nutritional intake, mouth care, oral function, and quality of life. OM increases the risk for bleeding and systemic infection and, when severe, can compromise the upper airway, requiring endotracheal intubation.

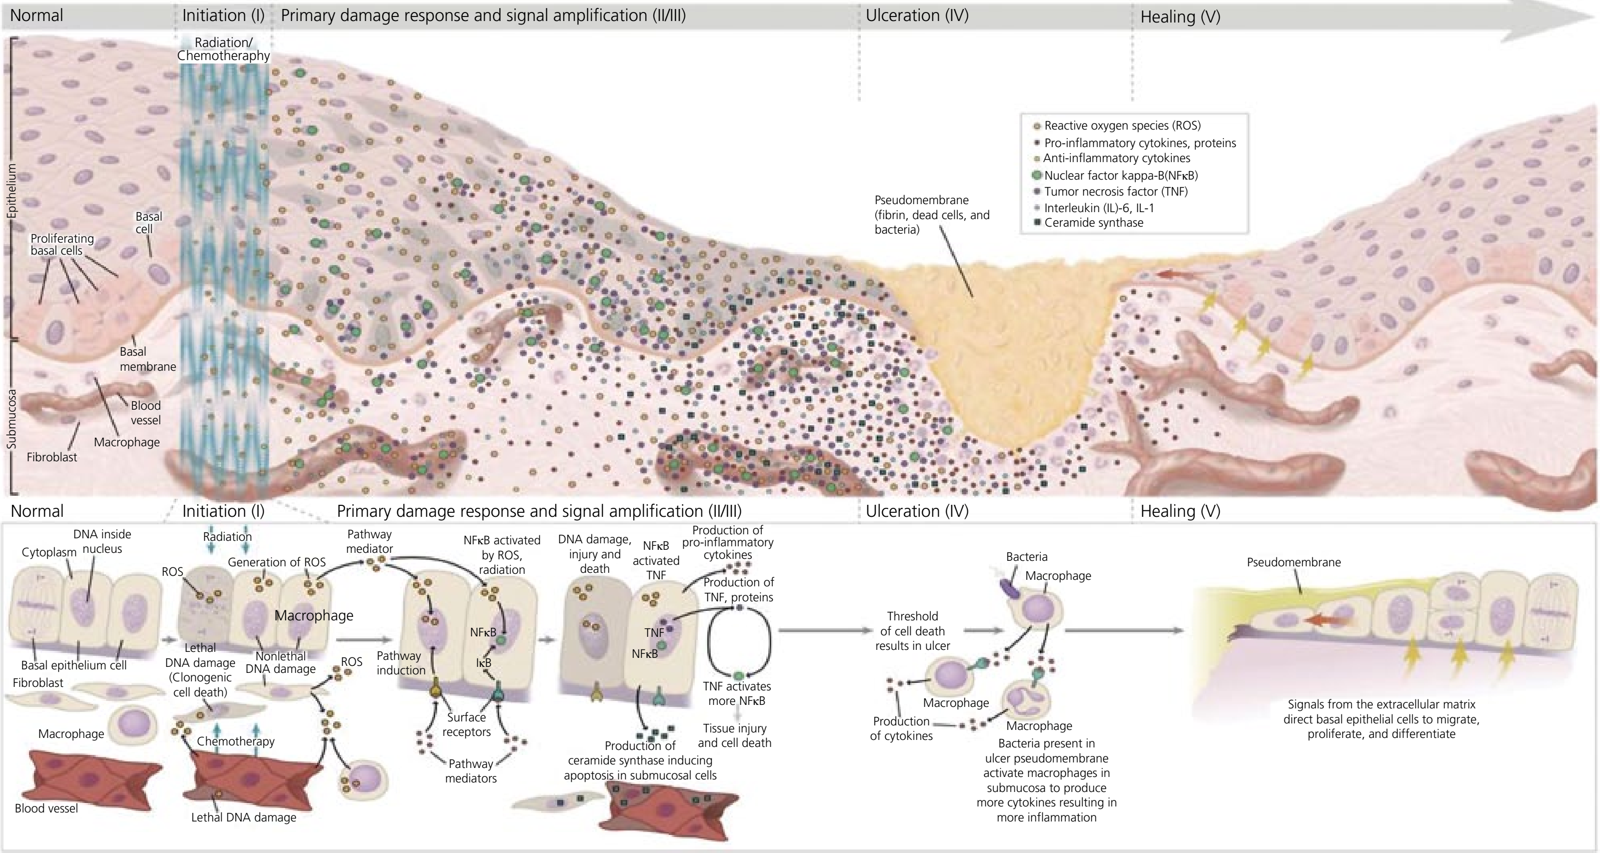
The current pathobiologic model of oral mucositis incorporates five stages [15] (Figure 101.1). Evidence supports the impact of both direct cellular damage from cancer chemotherapy and radiation, and derangements in proinflammatory cytokines [e.g. tumor necrosis factor-alpha (TNF-α), interleukin-1] and altered nuclear factor-kappa B (NFκB) transcription as possible key contributors to the development of OM. Further research addressed at understanding these mechanisms and related processes may lead to novel, molecularly targeted preventive or therapeutic strategies in the future.

Clinically apparent oral mucosal changes typically emerge 5–10 days after initiation of high-dose conditioning regimens. Initially, mucosal atrophy and erythema occur, notably on non-keratinized oral mucosa. Ulceration typically becomes most severe approximately 6–11 days after-HCT (Figures 26.6, 26.7, 101.2). The mucosa then gradually heals over the next 1–2 weeks. Oral mucosal sites most commonly affected include the lateral and ventral tongue, and buccal and labial mucosa. Severity of OM is primarily related to the type of conditioning regimen utilized. The degree of genetic match between the donor and patient (e.g. syngeneic, autologous, allogeneic, and unrelated donors) can affect the clinical expression of mucositis, since oral aGVHD can significantly confound the clinical presentation of conditioning regimen-related OM.

Mucosal injury can be accentuated by a number of factors including, but not limited to, salivary gland dysfunction, mucosal trauma (including trauma resulting from normal oral function), and infection or irritation caused by indigenous oral flora, acquired pathogens, and reactivation of latent organisms including herpes group viruses [e.g. herpes simplex virus (HSV)] [1]. Oral aGVHD should be included in the differential diagnosis for allogeneic HCT patients whose oral mucositis fails to demonstrate a clear trend for healing by 21 days post-HCT.

Oral mucositis management

Oral mucositis management can be challenging for the clinician and patient. Currently, management strategies are primarily directed towards symptom management [1]. The interventions are



Normal
Initiation (I)
Primary damage response and signal amplification (II/III)
Ulceration (IV)
Healing (V)
Radiation/
Chemotheraphy
Epithelium
Submucosa
Proliferating basal cells
Basal cell
Basal membrane
Blood vessel
Macrophage
Fibroblast
Pseudomembrane (fibrin, dead cells, and bacteria)
● Reactive oxygen species (ROS)
● Pro-inflammatory cytokines, proteins
● Anti-inflammatory cytokines
● Nuclear factor kappa-B(NFκB)
● Tumor necrosis factor (TNF)
● Interleukin (IL)-6, IL-1
■ Ceramide synthase

TNF activates more NFκB
Tissue injury and cell death
Production of ceramide synthase inducing apoptosis in submucosal cells
Threshold of cell death results in ulcer
Bacteria
Macrophage
Macrophage
Production of cytokines
Macrophage
Bacteria present in ulcer pseudomembrane activate macrophages in submucosa to produce more cytokines resulting in more inflammation
Pseudomembrane
Signals from the extracellular matrix direct basal epithelial cells to migrate, proliferate, and differentiate

Figure 101.1 The phases of mucositis following exposure of mucosa to radiation or chemotherapy can be arbitrarily arranged into five phases that in actuality can occur simultaneously.

Phase I: Initiation. Chemotherapy and radiation produce varying degrees of direct damage to DNA, usually through the production of reactive oxygen species. Additionally, there is simultaneous activation of other pathways involved with subsequent steps.

Phase II: Upregulation and message generation. Transcription factors such as nuclear factor-kappa B (NFκB) are activated to upregulate many genes in the endothelium, epithelium, fibroblasts, and macrophages, which results in the production of messaging and effector proteins including proinflammatory cytokines and enzymes. This results in apoptosis and widespread tissue damage.

Phase III: Amplification and signaling. Inflammatory cytokines can directly feed back to reupregulate transcription factors, such as NFκB, to set off a new wave of factors that can induce further damage throughout the epithelium and submucosa. Trauma and further cytokine release increase damage to epithelial surface.

Phase IV: Ulcerative/bacterial phase. This phase will usually peak between 6 and 12 days after transplant. With atrophy and ulceration of the mucosal surfaces, fibrin–exudate pseudomembranes form. These can become colonized by oral bacteria, which unfortunately is usually during the period of most profound neutropenia. Included in invading organisms are Gram-negative bacteria that can release endotoxins (lipopolysaccharide), which causes further release of cytokines from surrounding tissues and macrophages.

Phase V: Healing phase. Through signaling from the mesenchyme, signaling from the extracellular matrix promotes the recovery of the basal layer mucosal epithelial cells. The mucosal surface is renewed and ulcerations are healed. The return of circulating white blood cells (especially neutrophils) aids in clearing bacteria from tissue.

(a)

(b)

Figure 101.2 Severe oral mucositis occurring 8 days after hematopoietic cell transplantation following conditioning with VP-16, cyclophosphamide, and total body irradiation (World Health Organization mucositis score of 4). Bleeding ulcerations are noted on the anterior ventral area of the tongue (a) in this patient, with simultaneous pseudomembranous fibrin exudate-covered ulcers evident on the lower labial mucosa (b). (For a color version of this figure, please see the color plate section.)

Table 101.3 Mucositis management

Prevention of oral mucositis
- *Oral cryotherapy (ice chips)*: start holding ice chips in the mouth prior to administration of melphalan and continue for up to 6 hours
- *Radiation backscatter protection*: use vinyl mouth guards, cotton rolls, etc., to hold soft tissues away from metal restorations during delivery of radiation
- Epithelial growth factor (palifermin): for patients with hematologic malignancies scheduled to receive conditioning with protocols expected to have a high risk of grade III/IV

Symptomatic management of oral mucositis

Step 1
- Bland rinses (room temperature or chilled):
  - 0.9% saline solution
  - Sodium bicarbonate solution
  - 0.9% saline solution/sodium bicarbonate solution

Step 2
- Topical anesthetics
  - Lidocaine: viscous, ointment, sprays
  - Diphenhydramine solution
  - Other: doxepin solution, other antihistamines, benzydamine[a]
  - Mucosal protectant: hydroxypropylcellulose film-forming agents (Zilactin)

Step 3
- Analgesics
- Topical agents: benzydamine hydrochloride[a], doxepin rinse
- Opioid drugs: morphine, fentanyl, hydromorphone, others
  - Oral (regular release, time release)
  - Intravenous (bolus, continuous infusion, patient-controlled analgesia)
  - Transdermal patches
  - Oral transmucosal products

[a] Benzydamine is not licensed in the United States but is available in Canada and Europe.

based on the severity of tissue damage and symptoms, infection prevention and therapy, nutritional support, and use of standardized pain management decision matrices (pain management ladders) to determine the need for analgesics and narcotics (Table 101.3) [58]. An important advance in mucositis management was achieved with the US Food and Drug Administration (FDA) approval of keratinocyte growth factor-1 (palifermin) [16]. Clinical studies have shown that palifermin produces a significant reduction in several key adverse outcomes in patients undergoing autologous HCT who received palifermin prior to and immediately after conditioning with an aggressive ££TBI-based preparative regimen. The outcomes included a greater than 40% reduction in the incidence of severe OM (World Health Organization, grade 4).

Oral cryotherapy (ice chip therapy) is a technique that has been shown to be effective for reducing mucositis caused by single chemotherapeutic agents with relatively short half-lives delivered as bolus doses, such as melphalan [17]. Patients are instructed to start holding ice chips in their mouths 10 minutes prior to administration of the chemotherapy and then continue to hold ice in their mouth for the next 6 hours to induce local vasoconstriction and apparently reduce drug delivery to oral mucosal tissues. Oral laser therapy has also shown promise relative to efficacy and safety, but further research is needed [18,19].

Oral pain management

Since palifermin is the only agent currently approved for preventing mucositis, pain management strategies remain the primary means of managing OM symptoms until healing can occur. Symptom management and the prevention/management of factors that aggravate OM represent the primary objectives for HCT mucositis management. It is recommended that a “stepped” or “ladder” approach to pain management be utilized, such that a systematic stepwise protocol is used with treatments and agents being added to provide increasingly effective symptom relief for patients with mucositis [1,20]. Even though systemic treatments are usually required to manage severe mucositis, as each “step up” is added, it is important that patients continue to utilize the previous steps as part of the overall management strategy until mucositis has resolved.

Initially, the frequency of bland rinse use (saline and/or sodium bicarbonate) is increased to hydrate oral tissues, rinse away debris, and provide symptomatic relief for mild mucositis. Mucosal coating agents, such as antacid and kaolin solutions, can be added as discomfort increases. As mucosal breakdown and pain increase, the next step adds topical anesthetics. A wide variety of topical anesthetic agents is available, ranging from antihistamines (e.g. diphenhydramine) to topical local anesthetics (e.g. lidocaine, benzocaine) and analgesics (e.g. benzydamine, doxepin). One of the most common complications associated with topical anesthetic use is inadvertent mucosal damage due to trauma and irritation when trying to eat or carry out oral hygiene when the mouth is temporarily anesthetized. Generalized oral rinsing/gargling with anesthetics also carries the risk of impairing the gag reflex due to oropharyngeal anesthesia, which can result in aspiration and pneumonia. Therefore, local application to areas of ulceration may be more appropriate than extensive oral rinsing.

Although chlorhexidine can reduce bacterial colonization and help with gingivitis, there are conflicting reports relative to its ability to prevent mucositis. Current guidelines do not support the use of chlorhexidine to prevent oral mucositis [14].

Systemic pain medications, especially opioids, represent the last step of mucositis symptom management. These products are indicated when bland rinses and topical anesthetic fail to produce sufficient pain relief (see Chapter 100). OM typically produces gradually increasing pain that peaks between 6 and 11 days post-HCT. Morphine has generally been the most frequently utilized agent and has been found to be extremely effective when administered with patient-controlled analgesia. Opiates including hydromorphone, meperidine, and time-release oral or intravenous morphine and fentanyl can also be used.

Oral infections

The patterns and types of oral infection observed in HCT patients are, in general, similar to systemic infection risk patterns for HCT patients. However, advances in the prevention and management of infectious complications in HCT patients have dramatically reduced the incidence and impact of oral infections – antifungal prophylactic protocols have reduced the frequency of oral candidiasis, and prophylaxis for HSV and protocols to prevent cytomegalovirus (CMV) infections have significantly reduced the occurrence of oral HSV and CMV infections (see Chapters 86 and 87). Maintaining consistent and effective oral hygiene and the use of systemic prophylactic antibacterial protocols can dramatically reduce the risk for oral bacterial infections. HCT patients are at risk for oral infections until there is full immune reconstitution. The types and severity of these infections are related to a number of factors, including pre-transplant oral infections, the use of prophylactic infectious disease protocols, the degree and duration of immunosuppression, the degree and duration of mucosal damage (e.g. mucositis or GVHD), and salivary gland dysfunction. Phase II is the period of highest risk (early oral infections), although oral infections can be problematic long-term post-HCT (late oral infections).

Early oral infections

Myeloablation and immunosuppressive therapy directly increases the risk for both acute oral and systemic infections of oral origin [1]. The types of organism causing acute oral infections are primarily related to the colonizing oral microflora, acquired oral flora, and risk for reactivation of latent viruses. The risk of oral bacterial infection has been reduced with the implementation of standard oral hygiene protocols and improved bacterial prophylaxis and treatment. Opportunistic Gram-negative and Gram-positive pathogens and also Gram-positive streptococci and staphylococci, however, remain a substantial concern (see Chapter 84). Key risk factors for early oral infection include the degree and duration of immunosuppression, the severity and duration of damage to oral mucosa (OM and GVHD), salivary gland dysfunction, and patient adherence to oral hygiene protocols [1].

Fungal infections

Candidiasis is the most frequent oral infection occurring in HCT patients (see Chapter 85). The risk for oral *Candida* infections increases as the severity and duration of immunosuppression increases. However, with improved systemic antifungal prophylaxis protocols, the incidence and extent of oral *Candida* infections have decreased over the last decade. *Candida albicans* is considered to be the most pathogenic and most frequently isolated yeast species associated with oral infection, but other *Candida* species are increasingly being isolated. However, since *C. albicans* is a component of the normal oral flora, identification of *C. albicans* in culture specimens from oropharyngeal mucosa may only indicate colonization, and not infection, unless recovered in high numbers. It is important to correlate clinical findings of mucosal atrophy, erythema, and/or pseudomembranous plaques with the results of laboratory tests to identify yeasts both to determine the need to treat these infections and to judge infection response to therapy.

Pseudomembranous candidiasis is the most common clinical presentation for oral candidiasis and is usually described as white surface "debris-like" lesions that can be wiped off, most often involving the tongue, the buccal and labial mucosa, the tonsillar pillars, and the soft palate. *Candida* involvement of the lip commissures is noted as inflammation, chapping, and fissuring. The risk of oral candidiasis is highest during phase II and the first half of phase III. The most prominent risk factors for this infection are neutropenia, GVHD, GVHD therapy, salivary gland dysfunction, and use of broad-spectrum antibiotics. Food debris, pseudomembranous fibrin exudates, mucous secretions, and hyperkeratotic lichenoid changes related to GVHD may cause white "changes" that can be misinterpreted as pseudomembranous candidiasis.

A variety of topical antifungal strategies are available when localized oral candidiasis is present. Clotrimazole (troches or cream) or nystatin (oral solutions, pastilles, powder) can be used to control acute oral candidiasis. Systemic antifungal agents have demonstrated effectiveness against oropharyngeal candidiasis.

HCT patients are also at risk for oral infection caused by invasive fungal organisms, including aspergillosis and mucormycosis [21,22]. Systemic antifungal prophylaxis has significantly reduced the incidence of these infections. The tendency for these infections to result in aggressive local oral invasion and systemic spread, often with lethal outcome, is a major concern. Diagnosis of these infections often requires histopathologic examinations and culture of tissue specimens. Therapy requires the selection of appropriate systemic agents, often in conjunction with local surgical revision.

Viral infections

HCT patients are at high risk for acute oropharyngeal viral infections (see Chapters 86–89) [1]. During phase II and early phase III disease, oral viral infections are predominately caused by HSV. CMV infections can occur but are less common. Infections caused by varicella zoster virus (VZV), Epstein–Barr virus (EBV), and Coxsackie virus are extremely uncommon. Oral human papillomavirus (HPV) infections can be noted late post-HCT.

HSV reactivation early post-HCT can exacerbate mucositis and result in hemorrhagic, severe ulcerative lesions [23]. Clinically, HSV stomatitis can be difficult to recognize and is often confused with severe OM. As immune responsiveness recovers, HSV lesions appear as more classic focal ulcerations, often involving the attached gingiva and hard palate. Extraoral HSV lesions usually present with patterns similar to herpes labialis lesions.

The prophylactic use of acyclovir for HSV-seropositive patients has dramatically reduced the incidence of HSV reactivation. For patients not receiving prophylactic or therapeutic doses of acyclovir, or in instances where either oral acyclovir may not be absorbed adequately or resistant virus may be present, early diagnosis of HSV infection is important [24]. If not treated promptly, infection can cause significant oral pain and tissue damage, and it may even disseminate, with serious systemic sequelae. Diagnosis utilizes viral culture (including shell vial testing) or direct immunofluorescent staining of scrapings for ulcers (see Chapter 87).

CMV prophylaxis has dramatically reduced the incidence of oral lesions (see Chapter 86). CMV can cause oral ulcerative lesions during phases II and III [25]. CMV lesions have a non-specific clinical appearance, with a tendency for shallow-to-moderate-depth, irregular ulcerations covered with pseudomembranous fibrin exudate. In severe cases, lesions can be extensive and involve large areas of mucosa. Surface swab cultures often yield inconsistent results. Shell vial cultures can improve the possibility of detecting CMV, but histological examination using immunohistochemical tissue stains specific for CMV and biopsy materials is the most reliable technique to diagnose this disease. Ganciclovir and valganciclovir are the drugs of choice for treatment [26].

Bacterial infections

Bacterial infections in the HCT patient can be caused by “normal oral flora” or by nosocomial pathogens (see Chapter 84). Organisms typically classified as being of low virulence in immunocompetent patients can produce both local and systemic infections in HCT patients. Examples include Gram-positive organisms such as *Streptococcus viridans* and *Streptococcus mutans* [27].

Antibiotic prophylaxis in neutropenic HCT patients reduces mortality, episodes of fever, and the number of documented bacterial infections. The spectrum of infections tends to shift as new prophylactic antibiotic protocols evolve. However, the risk of viridans group streptococcal bacteremia and infection in patients with severe OM remains problematic, especially in those individuals receiving oral, non-absorbable quinolone antibiotics [12]. In addition, a number of pathogens, including *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Escherichia coli*, can be acquired. These highly pathogenic organisms can cause serious morbidity and can be fatal. Infection management strategies should involve preventive or therapeutic regimens that target these microbes. Microbiologic documentation of causative organisms is essential given the non-specific presentation of bacterial infections. It is important to recognize that secondary bacterial infection of all types of oral ulcerative lesions in immunosuppressed HCT patients can occur and complicate diagnosis and management.

Immunocompromised HCT patients with periodontal disease may develop acute periodontal infections with associated systemic sequelae. Although not frequent in HCT patients, these lesions can occur in subtle fashion, thus necessitating careful patient examination.

Late oral infections

Although the risk of infection decreases with immune recovery post-HCT, the oral cavity can remain at risk for a variety of infections as immunologic recovery progresses through late phase III and IV. Viral and fungal organisms cause most significant oral infections during these phases. Serious oral bacterial infections are less common, primarily developing secondary to periodontal or dental infections.

The most common oral fungal infection during these later phases is candidiasis, commonly presenting with pseudomembranous white plaques and striae; however, atrophic oral candidiasis can also occur. Since the appearance of oral GVHD and oral mucosal debris can be similar to that of candidiasis (Figures 84.13, 101.3, and 101.4), it is important that the specimen recovered from lesions be subjected to the appropriate laboratory identification of responsible organisms.

In phase III, oral HSV infections can range from herpetic stomatitis in severely immunosuppressed patients with widespread oral ulcerations to relatively minor herpes labialis lesions in patients with recovering immune function. CMV lesions are associated with a more compromised immune status and can be difficult to diagnose. Biopsy with immunofluorescence is usually needed to detect CMV associated with chronic painful oral ulcerations, especially in patients who have CMV reactivation.

VZV reactivation in HCT patients usually occurs after day 100 post-HCT, with the peak incidence between 3 and 12 months post-HCT. Orofacial lesions present with herpes zoster trigeminal dermatomal distribution patterns. Infection tends to occur during mid- to late-phase III and phase IV. Extended antiviral prophylaxis protocols have dramatically reduced the incidence of this infection.

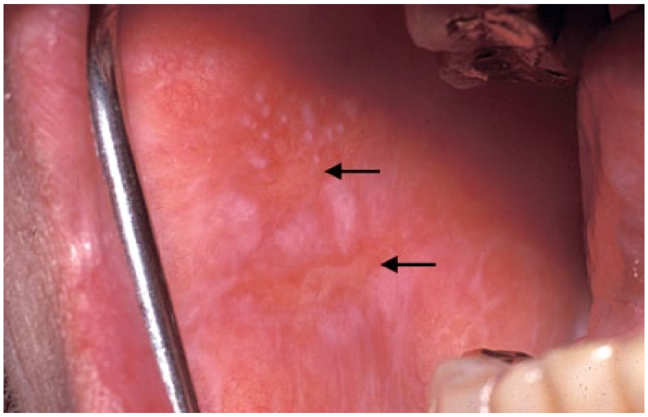

Figure 101.3 Oral chronic graft-versus-host disease in a patient 1 year post-HCT, with lichenoid hyperkeratotic changes (stria-, papule-, and plaque-like changes) associated with generalized atrophic and erythematous mucosal changes involving the right buccal mucosa. Small initial pseudomembranous fibrin exudate-covered ulcers are indicated by arrows. (For a color version of this figure, please see the color plate section.)

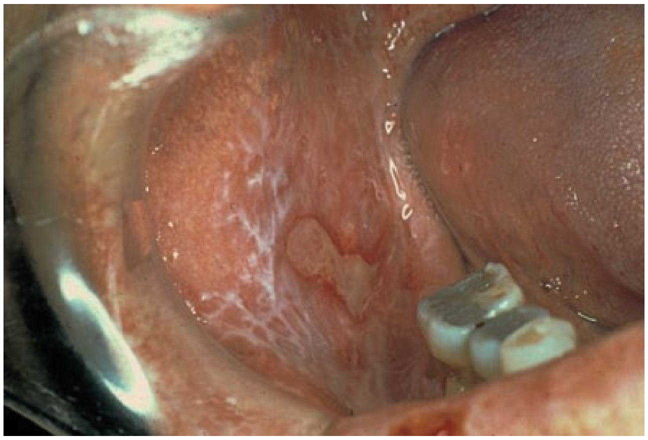

Figure 101.4 Severe oral chronic graft-versus-host disease showing distinct hyperkeratotic lichenoid striae and a pseudomembranous fibrin exudate-covered ulceration with intense surrounding inflammation in a patient approximately 18 months post-HCT. (For a color version of this figure, please see the color plate section.)

Chronically immunocompromised patients post-HCT, especially those receiving high-dose GVHD immunosuppressive therapy, are at increased risk for oral HPV infections [28]. Most cases appear to represent reactivation of latent virus, with patients reporting skin lesions prior to transplant. Oral HPV lesions can vary from exophytic oral verrucous vulgaris-like masses to a more flat condyloma acuminata-like appearance.

Oral hemorrhage

Oral hemorrhage in HCT patients is less common now as effective platelet support protocols and anti HSV prophylaxis have been developed. Risk factors for oral bleeding include thrombocytopenia, conditioning regime-associated vascular damage, use of anticoagulant therapy, presence of liver disease, and infections [29,30]. Local risk factors for bleeding include mucositis, infections, and trauma. Mucosal petechiae can be observed when the platelet count falls below 20,000/mL. Spontaneous gingival bleeding primarily occurs when there is active periodontal disease, especially when oral hygiene is inadequate.

Oral hemorrhage associated with thrombocytopenia is rarely a serious complication, although it can be both frustrating and alarming. Local measures are directed at decreasing blood flow along with promoting adequate clot formation, followed by clot protection until healing has occurred. Topically, treatment includes direct pressure applied via gauze soaked in vasoconstrictors (e.g. epinephrine) to reduce blood flow. Topical application of antifibrinolytic agents (ε-aminocaproic acid or tranexamic acid) with drug-soaked gauze can further help with clot stabilization. Clot-forming agents, especially hemostatic collagen products (e.g. microfibrillar collagen), fibrin glue, and chitosan can be used to organize and stabilize clots [31].

Salivary gland hypofunction

HCT conditioning regimens, especially those including TBI, anticholinergic medications, and the GVHD involvement of salivary glands, are major risk factors for salivary gland dysfunction post-HCT [32]. Hypofunction can be due to destruction of the secretory units of salivary glands leading to permanent reduction or alteration in saliva production [33,34].

The clinical signs of the salivary gland hypofunction can vary. Early post-HCT, patients may seem to have excessive saliva secretion that actually represents inadequate saliva clearance due to dysphagia and/or inadequate swallowing of secretions due to painful OM, pharyngitis, or nausea and vomiting triggered by swallowing oral secretions. More commonly, hyposalivation is observed to occur early post-transplant as a consequence of conditioning regime salivary gland damage; additionally, numerous drugs can suppress salivary gland secretions [35]. Saliva will often be more viscous due to decreased serous saliva secretion.

Xerostomia can significantly compromise the quality of life of patients, increasing the risk of oral lesions caused by trauma or the colonizing microflora. Strategies to promote mucosal moisturization and lubrication include frequent sipping of fluids, rinsing with bland oral rinses (0.9% saline or sodium bicarbonate rinses), and the use of artificial saliva and oral moisturizers. Sugar-free candies drops, mints, and gums can transiently increase salivary flow rates due to stimulation of glands through taste stimulation. Sialagogues (pilocarpine, cevimeline, and bethanechol) can be used to stimulate the salivary glands and improve oral moisturization [36,37] (Table 101.4).

Infection of the major salivary glands can occur when major salivary gland flow rates decrease and there is a retrograde spread of oral bacteria up ductal structures to involve salivary gland parenchyma. Treatment includes antibiotics along with stimulation of glands (e.g. lemon drops or sialogogues) and application of heat over the glands [38].

Table 101.4 Management of post-transplantation salivary gland dysfunction

---

Oral moisturization
- Frequent sipping of fluids
- Artificial saliva and oral lubricating agents

Stimulation of salivary glands
- Sugar-free candy, mints, and gum
- Sialagogues
  - – Pilocarpine (5–10 mg 3–4 times per day, maximum of 30 mg/day)
  - – Cevimeline (30 mg 3 times per day)
  - – Bethanechol (25–50 mg 3–4 times per day to a maximum of 150 mg/day)

Xerostomia decay prevention
- Plaque removal: tooth brushing, flossing, other oral hygiene aids
- Remineralization
  - – Topical prescription-strength fluorides[a]
    - 1.1% neutral sodium fluoride gel (preferred)
    - 0.4% stannous fluoride gel
  - – Brush on for 3–5 minutes, spit out, avoid rinsing for 20 minutes. Apply once per day
  - – Calcium/phosphate remineralizing solutions
- Topical antimicrobials
  - – 0.12–0.20% chlorhexidine oral rinse (use alcohol-free preparations whenever possible): rinse, hold in the mouth for 1–2 minutes and spit out
  - – Tetracycline (250 mg/4 oz water), minocycline (100 mg/4 oz water), or doxycycline (100 mg/4 oz water): rinse/hold 1 oz for 1 minute and then spit out; repeat 2–4 times per day
- Diet modification: reduce exposure to refined carbohydrates, sugars, etc.

---

[a] Non-prescription fluoride preparations are inadequate for moderate-to-high dental caries risk.

GVHD-induced salivary gland dysfunction results from ductal and acinar GVHD-induced tissue damage. Clinical manifestation of salivary gland GVHD involvement can additionally include mucoceles that can occur, with the labial and soft palate mucosa being the most frequently involved sites (Figure 84.15).

Conditioning regime-related salivary gland dysfunction will generally improve over the first 3–6 months after transplantation. Timely GVHD treatment appears to allow for some salivary gland recovery, although in some instances damage to the glands may be permanent [33,34]. Patients with chronic xerostomia are at increased risk of dental caries and should be placed on appropriate regimens to minimize dental plaque and provide for enamel remineralization via topical fluorides and/or remineralizing solutions [35] (Tables 101.2 and 101.4).

Oral GVHD

The oral cavity is frequently affected by GVHD [35]. Clinically, oral GVHD mimics a number of naturally occurring autoimmune disorders, including lichen planus, lupus erythematosus, and systemic sclerosis [35]. As noted above, GVHD involvement of the salivary glands can result in salivary gland dysfunction and xerostomia. General oral mucosal sensitivity and discomfort to normally tolerated agents (e.g. spices, mint flavoring agents, acidic foods) can be associated with oral GVHD. While the clinical presentation of oral GVHD is similar in both acute and cGVHD (mucosal erythema, atrophy, and white lichenoid hyperkeratotic striae, plaques and papules), patterns of changes are usually more distinct with cGVHD (Figures 84.13, 101.3, and 101.4). In more severe cases, pseudomembranous ulcerations can be noted. The posterior buccal and lower labial mucosa and lateral/ventral tongue are the most commonly involved sites.

In allogeneic HCT, early oral aGVHD is usually not discernible from OM until after 21–24 days post-HCT; early (prior to day 21) especially hyperacute, oral aGVHD will generally be attributed to severe OM that is slow to resolve. Oral aGVHD occurring between 28 and 120 days post-HCT will present with clinical changes with varying degrees of atrophy, erythema, and lichenoid hyperkeratotic lesions. Oral cGVHD mucosal changes are more distinct and pronounced. Oral GVHD can cause significant pain and produce an increased risk of oral infection. With extensive cGVHD, the extent and severity of oral lesions can become disabling. Chronic dental and periodontal infections have been noted to exacerbate oral GVHD, and elimination of these infections can often dramatically improve patients' oral status. Sclerodermatous changes can result in perioral fibrosis that decreases oral opening and interferes with oral function; in more severe cases, submucosal buccal fibrosis can further restrict oral opening. Oral secondary infections caused by HSV, CMV, and *Candida* species, or trauma, can exacerbate oral GVHD lesions and confound the diagnosis [35].

In 2006, the National Institutes of Health (NIH) published the Consensus Criteria for cGVHD [39]. The goal of this document was to standardize criteria for the assessment of cGVHD and to propose tools for scoring cGVHD organ involvement [39] (see Chapter 83). This scale has utility for determining oral cGVHD severity and then being used over time to judge the response to cGVHD therapy [40].

Symptomatic oral GVHD will often respond to topical immunosuppressive therapy, although more severe or recalcitrant cases require systemic immunosuppressive therapy. Topical management of oral GVHD can include topical application of steroids (rinses, creams, or gels), tacrolimus, and treatment with psoralen–ultraviolet A irradiation (PUVA) therapy (Table 101.5); while the effectiveness of topical cyclosporine and azathioprine have been reported with small case series, their effectiveness has not been generally appreciated. Topical therapy can reduce the symptoms from oral lesions and help resolve pseudomembranous ulcerations, but topical therapy will generally not produce complete resolution of oral involvement [41]. Extracorporeal photopheresis has been shown to reduce the severity of oral cGVHD [42].

As noted above, GVHD-induced salivary hypofunction is often noted, and although usually associated with oral mucosal lesions, it can occur independently of mucosal involvement. Salivary hypofunction interferes with oral function and can lead to symptoms of burning and mucosal irritation. Salivary hypofunction can increase the risk for dental decay due to the loss of specific salivary proteins that help control oral flora (which can result in a significant shift in oral flora to a predominance of dental decay-causing bacteria) and a reduction in salivary calcium and phosphates, which are important for remineralizing enamel and dentine. Patients need to be able to perform extremely efficient oral hygiene (brushing and flossing) along with using daily higher strengths of topical fluorides, calcium and phosphate remineralizing dental products, and possibly antibacterial mouth rinses. Attempts to improve salivary flow rates with sialagogues can increase resting salivary gland flow rates and improve patient comfort, but effects on oral health and caries reduction have not been demonstrated to date [35]. Permanent damage to salivary glands from GVHD will result in chronic xerostomia and decreased salivary flow rates.

Taste dysfunction

Taste dysfunction post-HCT is a neurosensory toxicity associated with conditioning regimens, medications (e.g. cyclosporine), and GVHD [43]. Decreased taste sensitivity is not only distressing for patients but also can affect their quality of life and can lead to food aversion, resulting in weight loss and nutritional decline.

Ageusia (loss of taste function) post-HCT results from widespread damage to taste receptor cells that results in insufficient detection of taste stimuli. HCT patients often describe symptoms consistent with dysgeusia (disordered or persistent unpleasant taste) due to lesser degree of taste receptor damage. Chronic GVHD flares have been associated with taste dysfunction; effective management of GVHD appears to support the recovery of taste acuity in these instances.

Normal taste function typically returns between 60 and 120 days following HCT. However, taste dysfunction can be persistent up to several years after HCT or even permanent [44]. Taste dysfunction in HCT patients is not preventable; management primarily consists of supportive care focusing on diet adjustment (food choices, preparation, etc.).

Neurotoxicity, neuropathies, and orofacial pain

Increased tooth hypersensitivity to thermal stimuli is frequently reported between 2 and 4 months after HCT. The mechanism is not understood, but possible etiologies may include gingival recession (dentine exposure), conditioning regimen toxicity, or cyclosporine toxicity. Symptoms usually resolve spontaneously within a few months. Topical brush-on fluorides, desensitizing toothpaste, and fluoride varnishes will generally reduce or eliminate symptoms.

Neuropathies involving the face and jaws can be noted pre-HCT due to tumor involvement of cranial nerves (e.g. leukemic infiltrates, multiple myeloma, lymphomas) and also neuropathies secondary to medications (e.g. lenolinomide, bortizomib, vinca alkaloids). It is important to obtain careful histories to identify potential risk factors. Reversibility of these neuropathies is unpredictable and management suggestions for painful neuropathies, especially medication-related neuropathies, will center around the use of agents such as carbamazepine, gabapentin, or pregabalin.

Oral neuromuscular complications resulting from treatment-induced neurotoxicity have been associated with a number of medications, including cyclophosphamide, steroids, cyclosporine, and tacrolimus (FK506) (see Chapter 105). Tongue and jaw muscle tremors, hot/cold tooth sensitivity, and taste dysfunction have been specifically associated with high-dose cyclosporine therapy. Reducing or discontinuing cyclosporine usually promotes resolution. Similar neurotoxicity problems have been associated with thalidomide.

TMD may present as facial pain, headache, muscle spasms or joint dysfunction, with headache and possibly referral of pain to the ear or throat. In most instances patients will report clenching or bruxing as a result of stress, sleep dysfunction, or, occasionally, central nervous system toxicity from selected medications. Masticatory muscle palpation tenderness, temporomandibular joint noises, and pain radiating to the ear are hallmark findings. The short-term use of muscle relaxants or anxiety-reducing agents plus physical therapy (moist heat applications, massage, and gentle stretching) will often resolve these symptoms.

Reduced-intensity conditioning regimen for HCT transplantation

Experience with reduced-intensity conditioning regimens (RICRs) for HCT continues to grow (see Chapter 20). Since the "intensity" of RICRs can vary significantly, the range and severity of oral complications can vary. For protocols utilizing fludarabine (150 mg/m^2) plus TBI (200 cGy), there is often no OM but salivary hypofunction and taste dysfunction are noted. With protocols of increasing intensity (fludarabine/cyclophosphamide/TBI and protocols

Table 101.5 Topical management of oral chronic graft-versus-host disease

(a)

Topical oral therapy	**Considerations for use**
Pre-use oral care	1. Rinse mouth with plain water; avoid normal saline 2. Try not to eat, drink or brush teeth with toothpaste for 15–20 minutes before use of topical agent
Rinses	1. Use adequate volume to easily coat oral tissues (5–10 mL) 2. Hold in mouth for 4–6 minutes, spit out. Rinses can be held longer if (a) oral lesions are more severe and/or (b) the patient is not able to use rinse the prescribed number of times per day 3. Avoid eating or drinking for 20–30 minutes after use
Gels	1. Dry lesion before application as this will improve adhesion to the lesion 2. Hold gel on lesions for 30–40 seconds: Gently apply gel to the lesion with a cotton swab or a clean fingertip. Apply like "icing a cake," do not "rub" into the tissue 3. Avoid eating or drinking for 20–30 minutes after use when possible Alternatively: apply ointment to a 2 × 2 sterile gauze and place on top of the lesion, keeping in place for 10–15[a] minutes. Remove gauze and avoid eating or drinking for 20–30 minutes after use when possible
Creams	1. Dry the lesion before applying 2. Warm a metal spoon in hot water, dry and place medication in the spoon to semi-liquefy 3. Apply softened/liquefied cream to the lesion 4. Avoid eating or drinking for 20–30 minutes after use when possible[a]
Ointments	1. Dry the lesion before application as this will improve adhesion to the lesion 2. Ointments can be warmed slightly as noted above for creams 3. Gently apply warmed ointment to the lesion with a cotton swab or a clean fingertip. The key is to apply like "icing a cake," not by trying to rub into the tissue 4. Avoid eating or drinking for 20–30 minutes after use when possible[a] Alternatively: apply ointment to a 2 × 2 sterile gauze and place on top of the lesion, keeping in place for 10–15[a] minutes. Remove gauze; avoid eating or drinking for 20–30 minutes
Inhalers	1. Dry oral tissues slightly 2. Use one or two "puffs" **without** inhaling – can be directed specifically towards lesions 3. For general oral GVHD, gently coat the mouth with the medication 4. If problems occur with oral candidiasis, in addition to prescribing antifungals, consider having the patient rinse the mouth 10–15 minutes after use

[a] Patients should avoid swallowing topical drugs after rinsing/applying.

Notes: (a) systemic uptake can occur from absorption through tissues or swallowing – patients may require monitoring of absorbed drug; (b) monitor mouth oral candidiasis; *Candida* cultures may be indicated.

(b)

	Agent	**Instructions**
Corticosteroids[a]		
Rinses	Dexamethasone	0.1–0.4 mg /mL rinse. 5–10 mL swish/held for 3–5 minutes. Spit out. Repeat 3–6 times per day
	Budesonide	0.3–0.6 mg/mL rinse. 10 mL swished/held for 15 minutes. Spit out. Repeat 2–4 times per day
	Betamethasone	0.5 mg tablet dissolved in 10 mL, held for 3 minutes, spit out. Repeat 4 times per day
Sprays/inhalers	Beclomethasone	1–2 puffs in mouth 2–4 times per day
	Fluticasone	1–2 puffs in mouth 2–4 times per day
	Betamethasone	1–2 puffs in mouth 2–4 times per day
	Triamcinolone	1–2 puffs in mouth 2–4 times per day
Gels, creams, and ointments	0.05% Clobetasol cream, ointment, gel, solution	Apply to lesions 2 times per day
	0.05% Halobetasol cream, ointment	Apply to lesions 2 times per day
	0.05% Fluocinonide cream, ointment, gel	Apply to lesions 2 times per day
	0.1–0.5% Triamcinolone cream	Apply to lesions 2 times per day
	0.05–0.1% Betamethasone cream, ointment	Apply to lesions 2 times per day
Non-steroidal immunosuppressives		
Rinses	Cyclosporine[b]	Rinse: 100 mg/mL, 5 mL swished/held for several minutes, spit out, repeat 3 times per day 1.5% gel applied to lesions 2 times per day
	Azathioprine	5–10 mg/mL, 5–10 mL swished and held for 3–5 minutes, spit out. Repeat 2–6 times per day
Gels/other	Cyclosporine[b]	0.5 mg/dL in bioadherent base
	Azathioprine	5 mg/mL in 3% methylcellulose gel, 1–2 mL applied to lesion 3–4 times per day
	0.1% Tacrolimus	Apply 0.5 inch to gauze, hold over lesion for 15–20 minutes 2 times per day. Monitor plasma levels
Phototherapy	PUVA	0.3 mg/kg psoralen followed by 0.5–6 J/cm^2 UVA radiation (dose increased as tolerated), 3–4 times per week
	UVB	0.02 mJ/cm^2 with escalating 0.02 mJ/cm^2 every 4th treatment
	Extracorporeal photopheresis (systemic/extracorporeal treatment)	
Dental infections	Aggressive prevention/treatment/elimination of all dental and periodontal infections; extract non-restorable involved teeth	

PUVA, psoralen–ultraviolet A irradiation; UVB, ultraviolet B irradiation.

[a] Anti-*Candida* prophylaxis may be needed, especially with inhalers.

[b] Cyclosporine is expensive and has met with mixed effectiveness.

Source: adapted from Schubert and Correa 2008 [35].

utilizing ≥300 cGy TBI), there is increasing frequency and severity of oral complications [45]. The severity and duration of neutropenia can vary with RICRs, hence the risk of oral infections can vary. Bacterial dental and periodontal infections remain a concern, but prophylactic antifungal, antiviral, and antibacterial protocols will generally reduce the risk for oral infections. Oral aGVHD can emerge post-HCT and oral cGVHD changes can be noted at the time of day 100 examinations, but oral cGVHD changes often will not become evident until immunosuppression is significantly reduced or withdrawn 4–6 months post-HCT with the clinical presentation similar to that seen in standard allogeneic transplant patients.

Evaluations for cGVHD: oral assessments

Standardized evaluation of the oral cavity of allogeneic HCT patients is recommended every 3 months after transplantation (see Chapter 83). Oral examinations obtained at regular intervals can provide important information relative to overall GVHD status. Clinical evaluations should be directed to determining the presence and severity of oral GVHD changes and also assessing overall oral health.

Initial examination

Initial cGVHD oral examinations should be obtained between 80 and 100 days post-HCT and should attempt to detect oral cGVHD changes and to assess the patient's general oral and dental health. Detection of oral GVHD changes at this time can aid in overall GVHD diagnosis and staging. Oral mucosal changes including erythema, atrophy, lichenoid hyperkeratotic striae, and pseudomembranous ulcerations are associated with oral GVHD [35] (Figures 101.3 and 101.4). Additionally, dental examinations should aim to detect the presence of or risk for dental, endodontic, and periodontal infections. It has been recognized that oral infections, including gingivitis, periodontitis, and dental abscesses, can aggravate GVHD. Patients should be encouraged to continue adequate oral hygiene. Patients with active decay or at risk for caries should be managed with a comprehensive program that can include topical fluorides, tooth remineralizing products, and antibacterial products [35]. Restorative and periodontal treatment should be prioritized and, if deemed immediately necessary, patients will need to receive prophylactic antibiotics along with strategies to reduce bacteremia and risk for aspiration pneumonia.

Generally, careful oral mucosal examinations are sensitive enough to detect the presence of oral GVHD. However, when clinical examinations are not conclusive, oral labial mucosal with minor salivary gland biopsies can provide data to support the diagnosis of GVHD [46]. Patients with clearly clinically evident oral GVHD mucosal changes will generally not require biopsy to confirm oral mucosal and minor salivary gland involvement by GVHD [40].

Long-term follow-up oral examinations

Follow-up oral examinations can provide important information relative to ongoing oral cGVHD activity and help judge response to systemic therapy. Oral pain/sensitivity and dryness related to oral GVHD, if identified, should be managed appropriately. The goal of topical oral GVHD therapy is to ameliorate symptoms and improve oral function and health [35] (Table 101.5). Assessment for chronic dental and periodontal infections needs to be made, and appropriate dental treatment to eliminate them needs to be carried out.

Antiosteoclastic therapy-associated osteonecrosis of the jaws

Antiosteoclastic therapy-associated osteonecrosis of the jaws (AOTONJ) is a recognized oral complication of patients receiving antiosteoclastic therapy with bisphosphonates and denosumab and is currently estimated to occur in 2–4% of patients receiving intravenous bisphosphonates and subcutaneous denosumab [47–49]. In the transplant setting, AOTONJ is most frequently seen in patients with multiple myeloma or patients who have been heavily treated previously for osteoporosis. AOTONJ is defined as the unexpected occurrence of non-healing exposed bone in the maxillofacial region that persists for over 8 weeks in patients who have received bisphosphonate or denosumab treatment without a history of radiation treatment to the involved bone. Although intravenous bisphosphonates has been most frequently associated with AOTONJ, oral bisphosphonates and subcutaneous denosumab for osteoporosis has also been associated with AOTONJ (Figures 101.5 and 101.6). Dental extractions, periodontal surgery, and denture trauma are the most commonly identified causes of AOTONJ, but spontaneous lesions can also occur [47,48]. Although the pathobiology of AOTONJ has not been fully established, it appears clear that osteoclast inactivation and secondary local infection are primary factors. A careful pre-HCT oral examination of patients receiving AOTONJ needs to be carried out [50]. Treatment of established AOTONJ involves the administration of topical and systemic antibiotics and pain medications. Advances in the surgical revision of AOTONJ lesions have been reported more recently [50]. It is important to note that the authors have not noted a worsening of AOTONJ lesions in patients following HCT, with most of these observations having been made in autologous HCT patients treated for multiple myeloma.

mTOR inhibitor oral ulcerations

Other than the use of sirolimus for treatment of cGVHD, tyrosine kinase inhibitors and mammalian target of rapamycin (mTOR) inhibitors are not commonly utilized with HCT protocols. However, these agents have clearly been associated with oral mucosal lesions that mimic recurrent aphthous ulcerations [51].

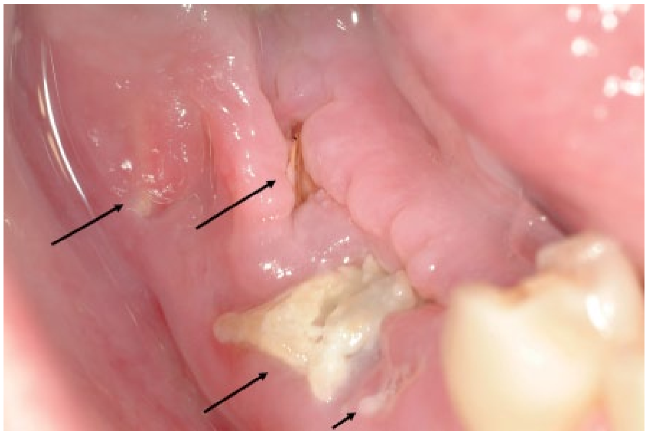

Figure 101.5 A 45-year-old male with a history of multiple myeloma who had been treated with intravenous zoledronate for 2 years prior to having two lower right molars extracted. He presented with three areas of bisphosphonate-associated osteonecrosis of the lower right mandible 6 months following the extractions. Lesions were non-painful and stable. Arrows indicate areas of bone exposure. (For a color version of this figure, please see the color plate section.)

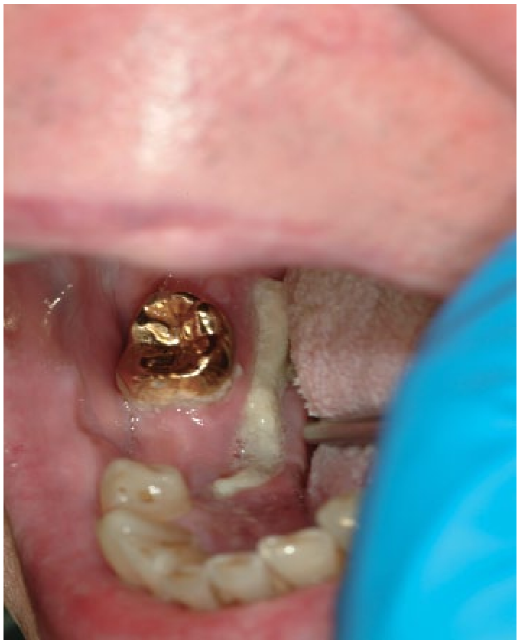

Figure 101.6 Bisphosphonate-associated osteonecrosis of the jaw involving the lower right lingual ridge in a patient with multiple myeloma treated with intravenous zoledronate monthly for 20 months. The patient's second bicuspid and first molar had been extracted 3 months earlier due to what was thought to be severe peridontal disease; the primary extraction site healed, but an extensive area of osteonecrosis developed along the mandibular lingual torus that was present lingual to the original extraction site. (For a color version of this figure, please see the color plate section.)

These lesions can be extremely painful and can be a dose-limiting toxicity. Early clinical reports suggest that these ulcerations can be responsive to topical, intralesional, and/or systemic steroids. Sirolimus-associated oral ulcers have not been reported, but could be responsible for additional mucosal damage in cGVHD patients being treated with sirolimus.

Routine dental care guidelines post-HCT

Complete dental examinations can be resumed generally between 120 and 180 days post-HCT and should include examination of teeth and periodontal tissues and radiographic assessments as indicated. However, resumption of routine dental treatment, including routine dental cleanings and restorations, is dependent upon the immune reconstitution and overall medical stabilization of the patient. Premature resumption of dental treatment can put the patient at risk for local infection, bacteremia, and aspiration pneumonia. In general, patients who have undergone autologous transplants can resume routine care approximately 5–6 months post-HCT with recovery of immune function; however, transplants utilizing CD34-depleted grafts or conditioning with fludarabine can result in slower immune recovery. Allogeneic HCT patients without cGVHD and who are no longer on immunosuppressive agents will generally require 9–12 months to recover adequate immune function before being candidates for routine dental care (immunosuppressive therapy should have been discontinued for approximately 6 weeks before resuming routine dental treatment). As long as the patient has active GVHD and is receiving immunosuppressive therapy, routine dental treatment should not be resumed, and if dental treatment is necessitated, infection prevention strategies should be used (see below).

If dental treatment is imperative for patients without full immune or hematologic reconstitution, it is important that the dentist and physician determine what supportive medical care is necessary, including prophylactic antibiotics, possibly immunoglobulin G administration, adjustment of steroid doses, and possibly platelet transfusions. Rinsing with chlorhexidine immediately before treatment is recommended. Prophylactic antibiotic regimens (American Heart Association endocarditis prevention protocols) appear to be efficacious, with regimens being extended if there is ongoing dental infection or if there is concern for delayed healing. Dentists should also utilize techniques to reduce the risk of aspiration (e.g. the use of rubber dams and high-volume suction), in addition to reducing the complexity of treatments and shortening treatment times.

Edentulous patients can generally receive prosthetic care once engraftment has occurred and their medical condition has stabilized. Either transitional or permanent dentures are typically feasible in these circumstances.

Orofacial/dental growth and development

Children younger than 16 years who undergo HCT are at risk for the development of abnormalities in their developing dental and/or skeletal structures [52] (see Chapter 102). Conditioning regimens, in addition to cancer therapy prior to transplantation, can damage tooth buds and result in a number of developmental abnormalities including enamel hypoplasia, root-growth alterations (root tapering and blunting, agenesis with premature apical closure), or complete agenesis. TBI conditioning regimens seem to be associated with increased risk of dental malformation compared with chemotherapy-only protocols. The younger a patient is at the time of transplant, the higher is the risk and extent of dental abnormalities (Figure 101.7).

Altered craniofacial skeletal development has also been noted following HCT and with altered orthognathic and facial development. The reduction in lower facial height reported in pediatric HCT patients could be due to the impaired dental development and the fact that young age is a risk factor for more severe dental disturbances [53], and also changes to facial and jaw skeletal development. It is useful to note that these skeletal changes appear to occur in a symmetric manner such that the child does not appear to have obviously hypoplastic jaws with corresponding esthetic changes; essentially, the face appears smaller but is relatively in proportion to the child's overall stature due to general retardation in growth.

Second malignancy post-HCT

The occurrence of new or second malignancies and lymphoproliferative disorders following HCT has long been recognized as a significant complication of HCT [48,50] (see Chapter 104). Oral cancers, especially squamous cell carcinomas and salivary gland tumors, are among the most common types of oral solid oral malignancies in both adult and pediatric long-term survivors of HCT [52,54]. Studies have shown that age at the time of HCT, cGVHD, and patients who had women as graft donors have an increased risk for development of second solid tumors. However, the presence of cGVHD was been reported as a risk factor for oral squamous cell carcinomas [55]. HPV infections may contribute to oral squamous cell carcinomas for HCT survivors, but the frequency and significance have not been studied or reported.

Unfortunately, oral dysplasia and malignancies can often be obscured by oral cGVHD or even mimic cGVHD, and only biopsy can discriminate between the two. Head and neck lymphoproliferative disorders have been noted, possibly with enlarged salivary

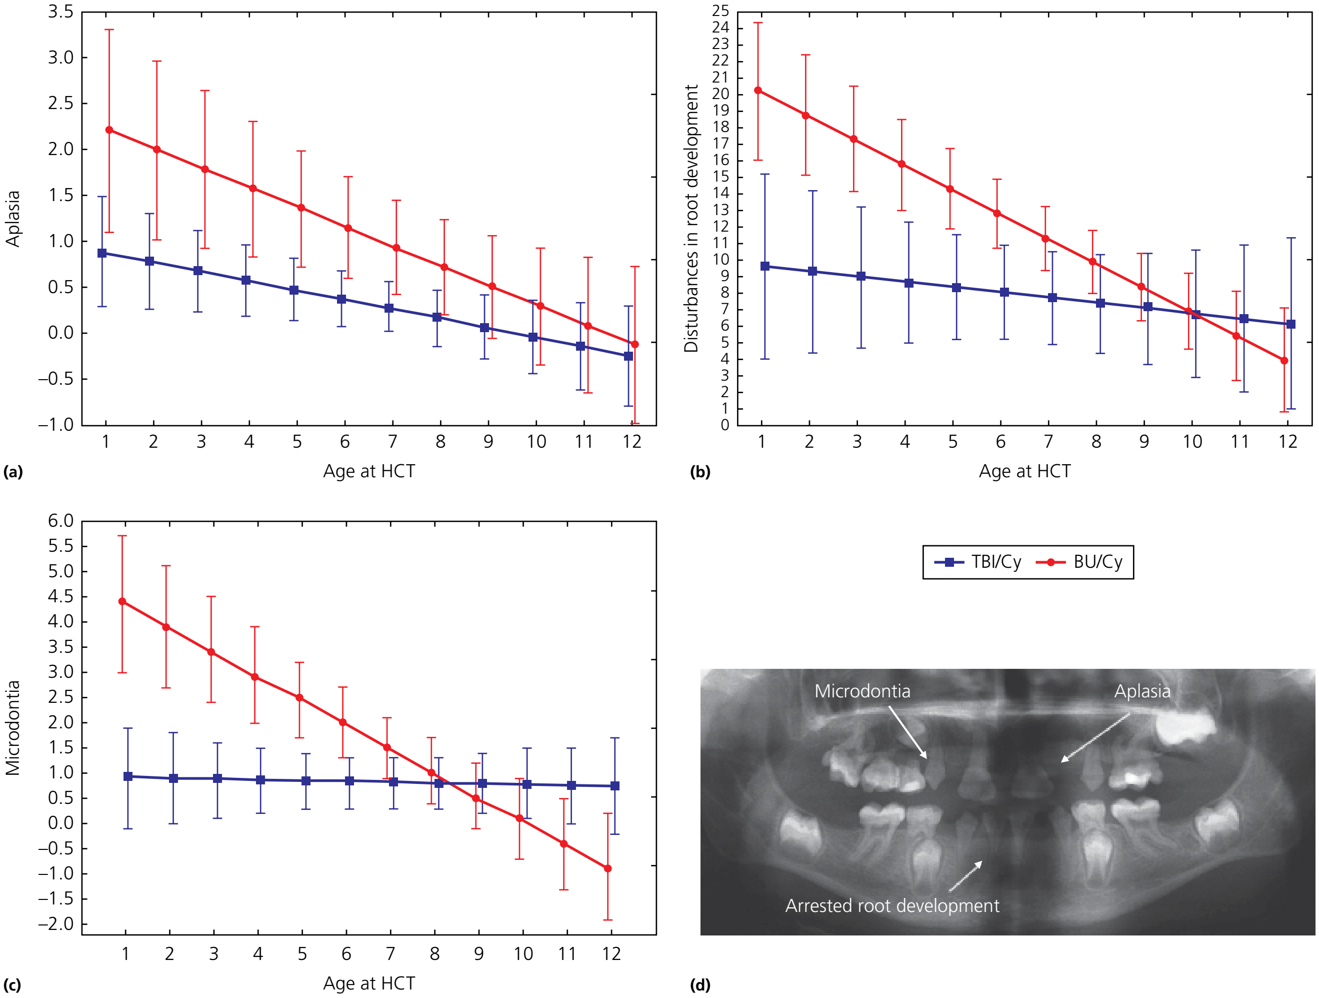

Figure 101.7 Disturbances in dental growth and development in long-term survivors of HCT. Conditioning regimes for HCT can cause severe disturbances in dental growth and development for pediatric HCT patients with TBI-containing regimes causing more problems than chemotherapy-only regimes. The younger the age at the time of transplant, the more significant the disturbance in dental developmental. (a) Number of missing teeth in children subjected to HCT by age. (b) Number of teeth with disturbances in root development by age. (c) Number of teeth with microdontia by age. (d) Panoramic radiograph showing arrested root development, microdontia, and aplasia of teeth in a pediatric long-term survivor post-HCT. Source: reproduced with permission of G. Dahllöf, K. Garming Legert, M. Remberger, and O. Ringdén Support Care Cancer (2012) 20 (Suppl 1):S226; 945. (For a color version of this figure, please see the color plate section.)

glands and cervical lymphadenopathy. Early detection of solid tumors has a crucial role in improving overall survival in this group of patients. Consistent and comprehensive oral soft tissue and head and neck examinations become a critical component of patient follow-up for all post-transplant survivors, with specific attention paid to early detection of potentially dysplastic and malignant lesions. Long-term survivors of HCT should be instructed to monitor oral lesions and changes appropriately: lesions not healing within 2–3 weeks should be carefully assessed and subjected to appropriate diagnostic testing. Clearly, biopsy is the only definitive way to differentiate between GVHD and malignancy in this setting [56].

Conclusion

The development of new technologies and strategies to prevent and manage HCT-related oral complications will have a significant impact on post-HCT patient recovery. Oral mucositis is one of the most significant and feared complications affecting early HCT recovery. However, preventing mucositis could reduce the risk for systemic infection, pain, and the number of hospital days, with a resulting improvement in the quality of life of patients, reducing hospital costs, and possibly reducing day-100 mortality. Additionally, improvements in management protocols for salivary gland dysfunction and taste dysfunction will also have a positive impact on the early phases of transplant recovery.

CHAPTER 102

Growth and Development After Hematopoietic Cell Transplantation

K. Scott Baker[1] **and Anna Petryk**[2]

[1] Fred Hutchinson Cancer Research Center, Seattle, WA, USA
[2] University of Minnesota Masonic Children's Hospital, Minneapolis, MN, USA

Introduction

Hematopoietic cell transplantation (HCT) is a curative therapeutic modality for an ever-increasing number of children and young adults with a variety of malignant and non-malignant disorders. However, an understanding of the late effects resulting from agents used in preparative regimens for HCT (chemotherapy and/or radiation therapy), along with knowledge of pre-HCT exposures, is necessary to appreciate and anticipate the effects on growth and development after transplantation.

Because the preparative regimens are designed not only to suppress the patient's immune system, but also to eradicate malignant cells, the doses of the agents administered are not limited by bone marrow toxicity. Historically, the most common regimens have utilized high-dose cyclophosphamide (CY) given alone or in combination with busulfan (BU), or other chemotherapy agents, and given with or without total body irradiation (TBI). Other chemotherapy agents used in preparative regimens include high-dose carmustine [1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU)], melphalan, etoposide (VP-16), fludarabine, and *N*-triethylenethiophosphoramide (thioTEPA). In addition to TBI, other radiation regimens include thoracoabdominal radiation (TAI) and total lymphoid radiation (TLI). The myeloablative doses of TBI have typically been 8–14.0 Gy, whereas the doses of TBI used for non-myeloablative transplant preparative regimens range from 2 to 6 Gy. Details of various myeloablative and non-myeloablative preparative regimens are discussed elsewhere in this book. It should be noted, however, that our current understanding of the impact on growth and development after non-myeloablative or reduced intensity HCT is basically unknown, although is anticipated to be significantly less than after myeloablative HCT.

Both high-dose chemotherapy and irradiation are known to affect the function of the neuroendocrine system, and therefore growth and development. The risks for the development of endocrine dysfunction depend on a variety of factors, including age at HCT, the type of conditioning regimen utilized, and the gender of the patient.

Normal growth and development require balanced endocrine gland function. Growth- and maturation-promoting hormones include thyroid hormone, growth hormone (GH), androgens, and estrogens. This chapter reviews the late effects that have been observed related to agents used primarily in myeloablative HCT preparative regimens on the endocrine function and the subsequent effects on growth and development of children and young adults.

Thyroid function

Normal thyroid hormone production is necessary for normal linear growth in young children. Consequently, suboptimal thyroid hormone production can contribute to decreased growth. Thyroid function is usually not impaired following conventional chemotherapy, but radiation to the thyroid gland has been associated with the development of compensated hypothyroidism, overt hypothyroidism, thyroiditis, and thyroid neoplasms [1]. Radiation of the thyroid may cause subsequent hyperplasia and induction of nodules and malignancies. The onset of thyroid dysfunction after irradiation usually begins as asymptomatic compensated hypothyroidism with elevated thyroid-stimulating hormone (TSH) and normal thyroid hormone production within the first year, and may progress to overt hypothyroidism with elevated TSH and subnormal thyroid hormone production over the next several decades.

Physical examination is often unreliable in detecting thyroid nodules. Fluctuations in serum thyroxine or triiodothyronine levels do not distinguish benign from malignant disease [2]. Ultrasonography detected thyroid abnormalities in 42 of 96 (44%) survivors of childhood cancer who received head and neck irradiation, compared with 15% with palpable lesions [2]. Thyroid nodules were detected by ultrasonography in 22 of the 96 (23%) patients and were significantly more frequent in patients whose thyroid exposure was more than 31 Gy.

The development of thyroid malignancies is another significant concern after HCT. While some report thyroid malignancy occurring between 1.5 and 6.0 years after radiotherapy exposure, other reports suggest a latency period of up to 40 years with a peak incidence occurring 15–25 years after irradiation exposure of 2–5 Gy [3,4]. The prevalence of thyroid malignancy in irradiated survivors of pediatric cancer is unknown. A 1991 epidemiologic investigation of 9170 patients who survived childhood cancer for at least 2 years reported a 53-fold increased risk of thyroid neoplasia [5]. Doses less than 2 Gy were associated with a 13-fold increased risk. Other studies suggest a radiation dose–response relationship and also a relationship to patient age at time of exposure, with younger age patients at highest risk [4,6].

The susceptibility of the thyroid to carcinogenetic effects of radiation is particularly apparent in younger individuals, and suggests

that children who have received TBI, TAI, or TLI in their HCT preparative regimens are at risk for development of thyroid abnormalities. Since no single historical factor, physical finding, or clinical laboratory result is pathognomonic of thyroid neoplasia, the use of ultrasound to detect subtle architectural changes in the thyroid gland may be useful as a screening tool to detect asymptomatic nodules.

Preparative regimens consisting of chemotherapy only

After HCT, thyroid function has usually been evaluated with TSH and free T4 plasma levels. Abnormal values often prompt further study, for example, thyroid autoantibodies. The majority of results from reported studies show that chemotherapy regimens including CY, BU plus CY, and other chemotherapy agents plus CY have not resulted in thyroid function abnormalities in the majority of patients, although these have all been limited by relatively small sample size of subjects [7–12]. Children given BU–CY preparative regimens and marrow transplantation for acute myeloid leukemia (AML) have shown a 3% incidence of hypothyroidism, suggesting that patients who received BU–CY are at low risk for development of hypothyroidism [9]. However, in a larger study, the Seattle group published data on 791 children who underwent HCT and survived for more than 1 year and found that by 10 years post-HCT 30% of patients developed hypothyroidism [13]. In multivariate analysis examining the impact of the preparative regimen (Figure 102.1a), there was no difference in the risk of thyroid dysfunction between patients who had received TBI compared with a BU-based regimen [hazard ratio (HR) 1.0 vs. 0.84, $p = 0.48$]. The highest risk of thyroid dysfunction was in the group who had received a preparative regimen that contained both TBI and BU (HR 1.7, $p = 0.009$), and the risk was reduced in those patients who received CY only in their conditioning regimen (HR 0.32, $p = 0.03$). Other significant risk factors from this analysis included local radiotherapy (spinal, mantle, and total lymphoid, HR 1.82, $p = 0.05$), age less than 10 years (HR 1.7, $p = 0.001$, Figure 102.1b), and malignant diagnosis (compared with non-malignant diseases) where the HR ranged from approximately 3.0 for myeloid or lymphoid malignancies to 15 for Hodgkin's disease (overall $p < 0.001$). Of note, however, is that in this analysis, the only patients to develop thyroid malignancy were those who had received TBI. In a larger analysis of over 4000 patients who underwent HCT for either AML or chronic myelogenous leukemia (CML) with a BU-based preparative regimen (no patient had received radiation therapy as treatment for disease before HCT or in preparation for HCT), no increased risk of developing thyroid cancer was identified [14].

Preparative regimens containing irradiation

Detailed evaluations of the hypothalamic–pituitary–thyroid axis have demonstrated that the major effect of irradiation is at the level of the thyroid gland and not at the level of the hypothalamus or pituitary gland [15]. Compensated hypothyroidism and overt hypothyroidism are both frequent events following TBI- or TLI-based preparative regimens [10–12,16–19]. In an analysis of thyroid function in 153 children with more than 5 years of follow-up, 16 (9%) developed overt hypothyroidism at a median of 2.9 years (range 1–10 years) and 31.4% developed compensated hypothyroidism at a median of 2.7 years (range 0.8–11 years) after transplant [11]. Thyroid dysfunction-free survival was 73.2% after 5 years and 59.2% after 10 years. Factors associated with the development of hypothyroidism were patient age less than 9 years, single-dose TBI, and HCT in second complete remission. Thyroid nodules not associated with malignancy developed in 10 of 35 patients evaluated at a median of 7.8 years. Other studies have also confirmed the fact that age younger than 9–10 years [13,20,21] at HCT is a risk factor for developing thyroid dysfunction after HCT, although as noted previously, TBI has not always been identified as an independent risk factor [13].

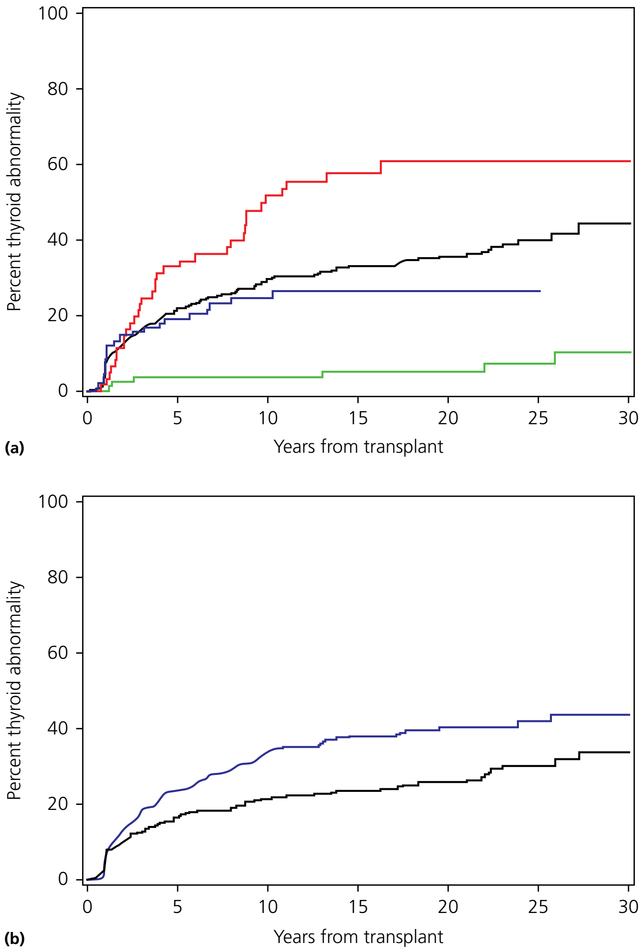

Figure 102.1 (a) Cumulative incidence of developing thyroid dysfunction after HCT according to type of preparative regimen received: from top to bottom, BU + TBI, TBI, BU, or CY only. (b) Cumulative incidence of developing thyroid dysfunction after HCT according to age at time of HCT. The bottom curve represents patients who received HCT between 10 and 17 years of age and the top curve patients between 0 and 9 years of age.

It appears that one of the strongest factors related to the risk of thyroid dysfunction after TBI exposure depends upon how the TBI is delivered and that the impact on thyroid function is much more significant in patients who received single-fraction TLI or TBI. Among children given 7.5 Gy single-exposure TLI or 7.8–10.0 Gy single-exposure TBI, compensated hypothyroidism or overt hypothyroidism developed in approximately 40–48% of patients, in contrast to an incidence of compensated hypothyroidism or overt hypothyroidism of approximately 15% observed among children after 12.0–15.74 Gy fractionated TBI [10,11,16–19]. The patients in these studies where single-exposure TBI was administered were followed on average for more than 8 years after radiation exposure, whereas those given fractionated exposure TBI were followed for a median of 4–6 years after radiation exposure. Although fractionated

TBI appears to result in a lower incidence of thyroid abnormalities, data from patients who received radiation but not HCT have shown that a risk for development of thyroid dysfunction and thyroid malignancies may be delayed several decades. The development of thyroid dysfunction has been associated with age at transplant, with age 0–9 years having higher risk than age greater than 10 years (HR 1.7, $p = 0.001$) [13]. Other factors such as gender or acute or chronic graft-versus-host disease (GVHD) have not been shown to have an impact on this risk.

Treatment

All patients in whom overt hypothyroidism develops should receive treatment with thyroxine, but the benefit of thyroid replacement in patients with compensated hypothyroidism is controversial. Although the carcinogenic potential of thyroid irradiation has been well documented, the ability of thyroid replacement to reduce the incidence of radiation-associated thyroid carcinoma remains unproven [1,22]. Recommendations from pediatric endocrinologists vary with respect to treatment of compensated hypothyroidism after irradiation therapy. Among patients in whom benign thyroid nodules develop after conventional irradiation therapy, treatment with thyroxine decreases the risk of recurrence of these nodules but does not decrease the risk of thyroid carcinoma.

Papillary carcinoma, toxic goiter, and an adenoma were observed between 4 and 14 years in six children after 10.0 Gy single-exposure TBI and in at least five after exposure to 12–15.75 Gy fractionated TBI [15]. All of these children had abnormal thyroid function, and none had received thyroid hormone therapy prior to discovery of the thyroid mass. The adenoma was found at autopsy, but the other patients were treated successfully with thyroidectomy or radioactive iodine thyroid ablation. Hence all patients who have received TBI, TLI, or TAI should be examined annually with physical examination, tests of thyroid function, and perhaps ultrasound.

The euthyroid sick syndrome should also be taken into consideration when interpreting the results of thyroid tests. In this condition, changes in thyroid hormone metabolism are associated with a severe, non-thyroidal illness, including in some cases HCT. The level of TSH decreases rapidly during the first few months after HCT but gradually recovers to normal by 6 months. Acute changes in thyroid hormone levels also gradually recover to pre-HCT levels by 6 months. Increased levels of cytokines, including interleukin-6 and tumor necrosis factor-alpha, post-HCT were found to correlate inversely with the levels of thyroid hormone. The euthyroid sick syndrome does not require specific thyroid hormone therapy [23].

Growth

Linear growth is a continuous and finely regulated phenomenon that is the result of the interaction of genetic make-up, nutritional factors, hormones (GH, thyroid hormone, sex steroids), and metabolism. The importance of each major factor varies with different periods of growth. Growth in infancy is largely determined by nutrition and metabolic factors. Growth in childhood is largely influenced by GH and in puberty by the synergistic action of GH and sex steroids. Impaired linear growth after HCT is multifactorial in origin and can be due to GH deficiency, hypothyroidism, hypogonadism, corticosteroid treatment, and poor nutritional status. The impact of GH deficiency on growth in children who received HCT is frequently difficult to determine since GH studies have not been performed consistently. Data are difficult to interpret as to whether intensive chemotherapy regimens with or without central nervous system (CNS) radiation are associated with persistent growth impairment, since often only growth rates are reported [24–28]. Some studies suggest that the intensity and duration of combination antineoplastic therapy in addition to CNS radiation and age at diagnosis influence patterns of growth [29–31]. The younger the child is at the time of CNS radiation, the greater is the loss of growth during puberty.

Several studies have compared growth outcome for children treated with conventional chemotherapy with or without cranial radiation and HCT. One study [32] of children with AML concluded that patterns of growth were similar between those who were treated with chemotherapy and those treated with HCT. Follow-up for the 26 patients in the chemotherapy group was 7.4 years (range 1.8–15.5 years) and that for the 26 patients in the HCT group was 5.6 years (range 2.0–15.4 years). None of the patients had GH testing performed, 11 chemotherapy patients had received 18–24 Gy cranial radiation, and nine HCT patients had received TBI. The change in height standard deviation (SD) from time of diagnosis to last follow-up was −0.43 for chemotherapy patients and −0.48 for HCT patients. A second comparison study [33] included 10 patients given chemotherapy, 18 patients given chemotherapy plus 18.0–24.0 Gy cranial radiation, and 15 patients given chemotherapy plus 12–15 Gy TBI and HCT. The change in height SD was −0.21 for the chemotherapy group,−1.26 for the chemotherapy plus cranial radiation group ($p = 0.0001$), and −1.33 for the HCT group ($p = 0.0008$). All patients had GH testing performed, and the only patients with GH deficiency were in the HCT group ($p = 0.003$). The third study evaluated infants diagnosed at less than 1 year of age with AML and acute lymphoblastic leukemia (ALL) [34]. Ten were treated with chemotherapy only, 17 received chemotherapy plus cranial radiation, and seven received HCT (six with TBI). The median change in height SD at 5 years after diagnosis was −0.9 for the chemotherapy group, −1.0 for the chemotherapy plus cranial radiation group ($p = 0.07$), and −2.3 for the HCT group ($p = 0.01$). Further follow-up for a small number suggested that height continued to decline with increasing time after diagnosis. Based on these and other studies, patients experience an average loss of 0.9–2.1 SD in height from the time of HCT to final height [35–39].

Recipients of chemotherapy only without cranial radiation have height losses that are substantially less than those observed after HCT using TBI-containing regimens [36,37,39–46]. CNS radiation has been associated with the development of GH deficiency, which appears to be related to the child's age at time of radiation, the radiation dose received, and the length of time elapsed after completion of radiation [47–49]. Radiation-induced GH deficiency is thought to be due mainly to hypothalamic damage, although the pituitary gland also shows sensitivity to radiation [47]. Some children, especially those with ALL, have received 18–24 Gy CNS radiation as part of their initial treatment prior to referral for HCT. When TBI is included in their preparative regimen, their total CNS radiation dose will usually exceed 30 Gy, the estimated threshold for development of GH deficiency [50], although even doses as low as 9–10 Gy may result in GH deficiency [51]. GH deficiency may be expected to develop 2–3 years after radiation in the majority of patients who received a higher total dose of CNS radiation, whereas GH deficiency may not develop in patients who received lower doses of CNS radiation for up to 5–10 years after radiation. Hence it may be anticipated that nearly all children who have received CNS radiation in addition to TBI are likely to develop GH deficiency, and that some children who received only TBI (particularly a single dose of TBI) just prior to or during their growth period may develop GH deficiency [42,43,52,53]. The latter group may not manifest a decline in the rate of growth until the third year after HCT. Fractionated TBI and TLI can also reduce growth velocity and final height, although the effect is less pronounced than after single-dose TBI [9,36,54,55]. Growth failure associated with TBI may also be due to direct radiation damage to the growth plates [56–58].

Because GH secretion is episodic, determination of GH levels involves the use of a stimulus to enhance pituitary GH secretion followed by multiple venous blood samplings. There is no consensus in the literature regarding a definitive GH stimulation test [59,60]. Although the 24-hour spontaneous pulsatile GH secretion test is considered by many to be the most physiologic assessment of GH secretion, it is impractical owing to the large volumes of blood required and the need for frequent sampling [61,62]. The 12-hour overnight sampling schedule has been shown to be well tolerated, reliable, and reproducible, but is less frequently used owing to the inconvenience of overnight hospitalization, extensive blood sampling, and lack of clear advantage over stimulated GH response [63,64]. Commonly used stimuli include exercise or pharmacologic agents such as clonidine, levodopa, arginine, growth hormone-releasing hormone (GHRH), and insulin [59,60,65–67]. The clinical diagnosis of GH deficiency is based on a combination of GH stimulation test, auxological criteria, biochemical tests, and radiologic evaluation [68]. Failure to attain a normal peak GH level (usually after two different stimuli), accompanied by a low insulin-like growth factor-1 (IGF-1) and IGF-binding protein-3 (IGFBP-3) levels, a height more than 2 SDs below the mean, decreased growth rate and height SD score, and a delayed bone age are typical features of classical GH deficiency, although not all of these criteria have to be met to diagnose GH deficiency [66,68]. For example, GH deficiency may be present in children whose height is above –2 SD, but significantly below the mid-parental height, especially if growth velocity is reduced. Also, IGF-1 and IGFBP-3 may not be reliable indicators of GH status after cranial radiation [69,70]. Furthermore, GH deficiency may develop over time, so GH provocative testing may have to be repeated even if the initial test was normal. Children who have received cranial radiation may have variable responses to the provocative stimuli, which may be due to the use of different pharmacologic agents, variations in the interval between radiation and testing, or neurosecretory defects [47,71,72].

Preparative regimens containing chemotherapy

Following preparative regimens with high-dose CY only, normal height SDs are usually observed, although pubertal growth spurt may be blunted [73]. When tested, normal levels of GH were detected. Some children with chronic GVHD treated with corticosteroids had decreased growth velocity during the time chronic GVHD was active and while being treated with corticosteroid therapy. Once chronic GVHD was controlled and corticosteroid therapy discontinued, catch-up growth occurred prior to growth rates returning to normal for age. Final height achieved for 26 girls and 25 boys was at a median of the 25th percentile (range 5–90th) for girls and the 50th percentile (range 5–95th) for boys. The European Group for Blood and Marrow Transplantation reported that mean final height SD among 26 patients prepared with CY only was –0.15 ± 1.68 [36].

BU, an alkylating agent frequently combined with CY in preparative regimens, is an agent that affects both dividing ands non-dividing cells, and crosses the blood–brain barrier [74]. The effect of BU on growth has been reported for children prepared with 14 mg/kg BU and 200 mg/kg CY prior to bone marrow transplantation (BMT) for thalassemia major [8,75]. Both studies found an effect of patient age at the time of HCT on subsequent growth. Among 47 patients evaluable for final adult height, the 26 patients who were aged 7 years or less at HCT had a final adult height consistent with the mid-parental height, whereas the 21 patients who were over 7 years of age at HCT failed to achieve their full genetic height potential. It is not possible from these data to determine if this effect was secondary to BU exposure or whether the correction of thalassemia at an earlier age had a positive impact on growth.

Among children prepared with 16 mg/kg BU and 120 mg/kg or 200 mg/kg CY prior to BMT for AML, similar data have emerged. Data among the AML children who had not received prior CNS radiation have generally demonstrated normal growth velocity [9,15,36,43,46,76,77]. Studies have shown that height SD improves following HCT. One study of 23 children found no significant difference between height SD at HCT and yearly height SD from 1 to 5 years post-HCT, with a mean height at HCT of –0.38 SD to a mean height at 5 years of –0.11 [76]. The European Group for Blood and Marrow Transplantation reported final adult height to be –0.38 ± 1.16 SD for 10 children [36]. We have observed the final adult height *z*-score to be –0.3 to –0.4 (±1.46) SD or height at a mean of the 30th percentile for both boys and girls. Height SD and height growth velocity are shown in Figures 102.2 and 102.3 for 47 boys and 39 girls following 16 mg/kg BU and 120 or 200 mg/kg CY. Both girls and boys had blunted pubertal growth spurt. The impact of chronic illness on height has been demonstrated in one report of 30 children evaluated at 3 years after HCT. The 12 children with no post-HCT complications had a change in height from HCT to 3 years of –0.2 SD, whereas the 18 children with complications (mainly chronic GVHD) had a change in height of –1.7 SD ($p = 0.001$), demonstrating that factors other than the preparative regimen have significant impact on the child's growth [77].

Thus, the impact of chemotherapy-only preparative regimens on growth is less clear. Chemotherapy-only regimens usually do not adversely affect height, although there are rare reports of growth impairment and GH deficiency after BU–CY [8,43,46]. Although BU crosses the blood–brain barrier and can produce dose-related neurotoxicity, a direct causality between the dose of BU and impaired GH secretion remains to be proven [78,79].

Radiation-containing preparative regimens

Growth rates

Growth impairment after TBI has been well documented [9,10,15,35–37,40–46,55,57,69,73,80]. Children given single-exposure TBI usually have been the group with the greatest incidence of growth rate impairment, which often has also been associated with decreased GH production. Fractionated TBI was initially thought to have a growth-"sparing" effect, but these children have demonstrated decreased growth rates and decreased height SD scores [39,55,81,82]. One study comparing height SD scores for 26 patients given 9–10 Gy single-exposure TBI with those for 23 patients given 12–14.40 Gy fractionated-exposure TBI found that all had decreased height SD scores. The patients with single-fraction TBI had a change in height SD scores from −0.29 to −0.90 ($p = 0.0001$) between 1 and 3 years after HCT, whereas the height SD scores for patients who received fractionated TBI changed from −0.09 to −0.22 ($p = 0.02$) between 1 and 3 years after HCT [55]. A second study reported the mean cumulative height change during the first 3 years after TBI among prepubertal children not given cranial radiation. These height changes were significantly worse for the 11 patients given 10 Gy single-exposure TBI ($p = 0.001$) (mean height change −1.4 SD) compared with seven children given 12 Gy fractionated TBI (mean cumulative height change −0.4 SD, p = NS) [81]. A third study reported no differences in height SD at 8 years after single-exposure TBI for 81 children. The mean height changes for 237 children who had not received cranial radiation prior to 12.0–15.75 Gy fractionated TBI were −1.0 SD at 3 years and −1.3 SD at 6 years, and among the 79 who received cranial radiation and fractionated TBI the mean height changes were −1.4 SD at 3 years and −1.7 SD at 6 years. Prior cranial radiation and years post-transplant were the only factors found to influence subsequent height SD scores significantly.

Patient age at transplant has been found to be a significant factor in predicting final adult height [36,37,39,40]. Studies have shown that children less than 10 years of age at time of transplant have the greatest risk for growth failure and significantly decreased final adult height. Patient's gender has also been found to have a significant influence on final adult height, with boys being at a greater risk of growth failure than girls [37,39,40]. Other reports have confirmed the negative effect of young patient age and male gender on final height [39,83]. Boys had a significant decrease in sitting height and leg length, whereas girls had a decrease in sitting height SD score that was not accompanied by a reduction in leg length [83]. The decreased sitting height in both boys and girls is most likely related to the effect of radiotherapy on the spinal growth, which is greater than the impact on the leg growth. These investigators found that the mean height SD loss between TBI and final height was −1.1 SD for girls and −1.5 SD for boys.

Growth hormone

The total height gained from GH therapy is inversely related to patient age at the start of treatment and positively correlated with the duration of therapy. GH has additional beneficial effects for the growing child in addition to improving linear growth. Children with GH deficiency are at risk for decreased bone mineral density due to reduced osteoblastic activity, leading to decreased bone mineral accrual [84–86]. Studies in children with GH deficiency have shown that bone loss is reversed with GH therapy [87]. GH also affects body composition and lipid profile. Those who are GH deficient have reduced lean body mass, increased visceral obesity, dyslipidemia, and an increase in cardiovascular risk factors and cardiovascular mortality [88–94]. Treatment with GH has resulted in improved lean body mass and improved cardiovascular risk profile among children not undergoing HCT [95–98].

The incidence of GH deficiency after TBI and HCT varies from 20 to 85% depending upon differences in time of testing after HCT, preparative regimens received, inclusion of patients with and without cranial radiation, and use of different methods of GH testing [18,44,53,57,66,69,99,100]. Even though GH deficiency has been observed, fewer than half have received GH therapy. Retrospective studies have shown that height SD is significantly lower than predicted based on height at HCT and mid-parental height [37,40,55]. Some authors have concluded that GH therapy was not needed because final height SD was not more than 2 SD below the mean, or because GH-treated children did not have significantly improved growth [36,37]. Others have reported, based on a retrospective study, that GH therapy does not benefit children, but most of the children had received less than 1 year of GH therapy [35]. One study reported on 13 children, eight of whom received prophylactic cranial radiation, who were given GH, which restored normal height velocity but without "catch-up" growth [53]. The final height SD scores remained impaired. In these children, a mean of 3.2 years had elapsed between TBI and initiation of GH therapy, which began at a mean age of 12.2 years (range 5.8–18.2 years).

The poor response to GH therapy has been attributed to factors such as spinal radiation, early puberty, suboptimal GH dosing

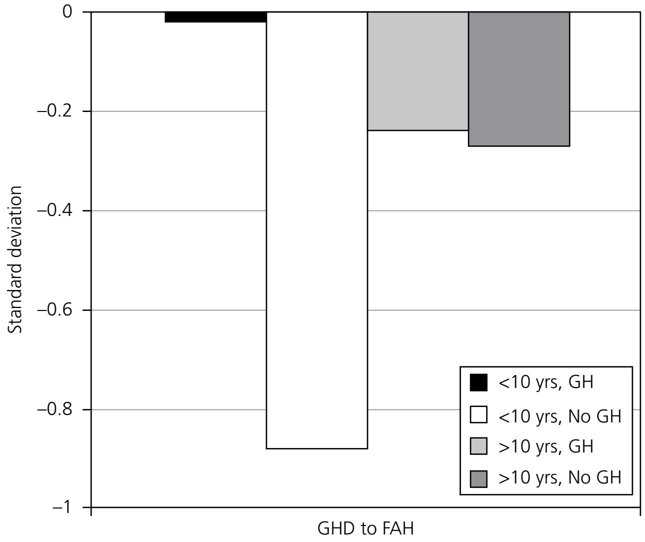

Figure 102.4 Final height SD score for 42 children with growth hormone deficiency (GHD) treated with GH when less than 10 years of age (black box) or more than 10 years of age (light gray box), and final height SD score for 48 children with GH deficiency not treated with growth hormone when less than 10 years of age (long white box) or more than 10 years of age (dark gray box). FAH, final adult height.

schedules, variable monitoring practices, and older age of most patients when GH therapy was initiated. However, improvements in growth and final height can be achieved with contemporary dosing regimens of about 0.3 mg/kg/week in prepubertal children with adequate pubertal dose increase to promote growth spurt [42,57,101,102]. In a more contemporary study of GH-deficient children transplanted at a single transplant center with fractionated TBI, GH treatment was associated with significantly improved final height [39]. Children who were treated with GH gained on average 0.9 SD in height compared with untreated children. The effectiveness of GH treatment was inversely associated with patient age at the time of GH treatment and positively associated with the duration of treatment. Younger patients (<10 years of age) responded better to GH treatment than older patients, and females responded better than males. Interestingly, a history of cranial radiation did not have a significant impact on the response to GH therapy. Figure 102.4 shows how the final height for 42 children with GH deficiency treated with GH and 48 children with GH deficiency who were not treated with GH was influenced by age at the time of TBI [39]. A beneficial effect of GH treatment on either short-term growth [57] or growth up to final height [38] has also been reported by other authors.

Initially, treatment with human GH was restricted owing to the limited supply of the drug, but with the availability of recombinant GH, access no longer is a problem. Reports of leukemia occurring in patients treated with human GH have raised concern that there might be a causal relationship between GH therapy and development of leukemia [100,103–105]. The Lawson Wilkins Pediatric Endocrine Society and the Human Growth Foundation of the United States convened a workshop in 1988 to review known leukemia cases in 22,000 GH-treated patients in Europe, North America, Japan, and Australia since 1959 [106]. Of 15 cases of leukemia, four occurred after a brief period of GH therapy or there were compelling reasons to suspect another cause for the leukemia. The 11 suspect cases developed during 150,000 patient-years of risk, including the periods of treatment and follow-up, so that the incidence of leukemia was approximately one per 21,000 patient-years at risk. The expected annual leukemia incidence among treated patients with hypopituitarism was estimated to be one per 42,000 patient-years. After review of all the available data, workshop participants concluded that there might be a small increase in leukemia incidence associated with the GH treatment of GH-deficient patients, but it was not clear that this incidence was directly related to GH therapy. In absolute terms, a current estimate of individual risk, assuming a 10-year GH treatment course, would be one per 2400 (0.042%), which is no different from the Surveillance and End Results estimate of new cases of leukemia reported in the United States (1:2400 per year).

Sklar et al. studied 361 GH-treated cancer survivors from among 13,539 survivors enrolled in the Childhood Cancer Survivor Study and compared risk of recurrence, risk of second neoplasms, and risk of death between survivors who did and did not receive GH treatment [107]. With respect to disease recurrence, the data have been largely negative. Relative risk of a first recurrence was 0.83 ($p = 0.65$) for those treated versus not treated with GH when adjusted for age at diagnosis, radiation therapy, and chemotherapy. For CNS tumor survivors, the risk of disease recurrence was actually significantly lower for patients treated with GH than patients not treated with GH. The risk was not different between GH-treated and not treated patients for other diagnoses also, including acute leukemia [49]. However, the risk of second neoplasm was slightly increased in patients treated with GH (5.5% of those treated with GH developed a second neoplasm). All second neoplasms were solid tumors; there were no cases of secondary leukemia. The most prevalent types of tumors were osteosarcoma (particularly in leukemia survivors) and meningioma (particularly in patients with CNS tumors). The risk of death was similar between GH-treated and not treated patients. Osteosarcoma occurred in three of the 122 leukemia/lymphoma survivors treated with GH compared with only two cases in >4500 leukemia/lymphoma survivors who did not receive GH. The study by Sanders et al. showed no difference in the development of recurrent leukemia or secondary malignancies between those HCT recipients who received GH therapy and those who did not [39]. The incidence of osteochondroma/exostosis was higher among GH-treated patients [39].

Puberty

Puberty, a transitional stage from a sexually immature to a mature sexual state, is accompanied by significant changes in gonadal and growth hormonal activity, development of secondary sexual characteristics, and increased growth velocity. There is considerable variation in the timing of pubertal events. Pubertal development is usually closely correlated with osseous maturation as measured by bone age. An intact hypothalamic–pituitary–gonadal axis is required for initiation and completion of puberty. The normal pubertal growth rate is usually 1.5–2 times greater than prepubertal growth rate [108]. Sex hormones indirectly stimulate linear growth by increasing endogenous GH secretion [109]. This stimulation leads to increasing circulating and tissue levels of IGF-1, which activates growth at the level of bone and cartilage.

Hypogonadism is common after HCT [52,110]. Hypergonadotropic hypogonadism (primary gonadal failure) is more common than hypogonadotropic hypogonadism (due to hypothalamic–pituitary dysfunction). In girls, ovarian failure is diagnosed by increased plasma follicle-stimulating hormone (FSH) and/or luteinizing hormone (LH) concentrations [111]. Ovarian failure impairs both fertility and estradiol production. In boys, seminiferous tubule dysfunction (characterized by an increased plasma FSH concentration and smaller testicular size) is more common than Leydig cell dysfunction (manifesting as low testosterone level and increased plasma LH concentration) because the germinal epithelium of the testis is more vulnerable to chemotherapy and radiation than Leydig cells [9,112]. Thus, in males, fertility may be impaired, but testosterone production may be normal. Precocious puberty is much less common than delayed puberty [38].

Clinical presentation of impaired sex hormone production depends on the age and pubertal stage at the time of HCT. Younger patients may have delayed puberty, whereas older patients may show asynchronous or incomplete pubertal development, primary or secondary amenorrhea, and infertility due to azoospermia or premature menopause. Delayed or incomplete puberty occurs in about 57% of females and 53% of males [52,113–115]. In general, premature ovarian failure occurs in 65–84% of females after HCT [111–113,116–118] and testicular failure occurs in 48–85% males after HCT [52,111,112,119,120], although the incidence varies depending on the therapeutic regimen. Sex steroids are also required for the growth spurt during adolescence. In the absence of pubertal sex hormone secretion, the increased growth velocity associated with the pubertal growth spurt is substantially blunted, resulting in a decrease in final adult height [121]. Treatment with low to moderate doses of sex hormones promotes increased linear growth, but physiologic adult doses of sex hormones result in a greater influence on skeletal maturation, with resultant compromise in final adult height via the mechanism of premature epiphyseal closure.

Gonadal hormone production and germ cell viability are affected by high doses of alkylating agents and irradiation, with variables related to patient age, gender, and type and dose of therapy [122]. Impaired gonadal function affects 16% females and 14% males after CY alone, 72% females and 48% males after BU–CY, and 57–71% females and 58–81% males after TBI, depending on the dose [52,113–115]. Azoospermia develops in prepubertal boys who have received a cumulative dose of more than 350 mg/kg CY, whereas doses of 200 mg/kg or less result in minimal alteration of spermatogenesis. Irradiation to the prepubertal testes results in damage to the germinal epithelium that does not become apparent until the usual time of puberty [123]. Boys who have received more than 24 Gy of testicular irradiation have delayed or arrested development of secondary sexual characteristics, with elevated gonadotropin and low testosterone values. Primary ovarian failure usually occurs following total cumulative doses of more than 500 mg/kg CY to prepubertal girls [122]. Hence both ovaries and testes are sensitive to gonadotoxic effects of chemotherapy and radiation.

Preparative regimens containing only chemotherapy

Following 200 mg/kg CY and BMT for aplastic anemia, 31 of 32 girls and 28 of 31 boys who were prepubertal at the time of administration of CY were followed past the age of 12 years to evaluate pubertal development [52,112]. Nearly all of these children demonstrated normal age-appropriate progression through puberty. Three girls with delayed pubertal development had Fanconi anemia and eventually developed normal secondary sexual characteristics and normal LH, FSH, and estradiol levels, and two girls showed delay due to chronic GVHD therapy. Among the 26 girls with normal age-appropriate development, menarche occurred at a median of 12.5 years of age (range 11–16 years), and the five with delayed development had menarche occur between 16 and 19 years of age. Thus, prepubertal patients are more resistant to gonadotoxic effects of CY and are more likely to retain or recover ovarian function [124]. The three boys with delayed pubertal development had chronic GVHD and did ultimately develop normal secondary sexual characteristics with normal LH, FSH, and testosterone values. Younger age is also somewhat protective in boys [124].

Gonadal function after 14 mg/kg BU plus 200 mg/kg CY and allogeneic BMT for thalassemia has been reported for 64 prepubertal patients (31 girls and 33 boys) who ranged in age from 9.3 to 17.2 years [125–128]. Twenty-five girls had evidence of primary ovarian failure, with elevated gonadotropin levels, and six girls had hypogonadotropic hypogonadism. All girls had low estradiol levels both before and after transplantation and required hormone supplementation for development of secondary sexual characteristics. Among the 33 boys, post-transplant LH and FSH concentrations were within normal limits for 23 boys, but abnormal with either elevated LH and FSH or low LH and FSH in 10 boys. However, after gonadotropin-releasing hormone stimulation, three had normal responses, two had elevated FSH responses, and 10 had low responses. These gonadal function results must be interpreted with caution, however, because patients with thalassemia treated with chelation and transfusion therapy frequently show delayed or absent puberty.

Pubertal development has been evaluated among children transplanted for malignancy who received 16 mg/kg BU plus 120–200 mg/kg CY [125,129,130]. These data demonstrate that BU is highly toxic to prepubertal, particularly female, gonads. Probability of recovery of ovarian function is extraordinarily low or non-existent in patients who received BU–CY [9,76,112]. Boys who were exposed to CY-only conditioning regimens are more likely to recover testicular function (24–90%) than those exposed to BU–CY (6.5–50%) [112,119].

Preparative regimens containing radiation

The development of secondary sexual characteristics among children who were prepubertal at the time of TBI administration but more than 12 years of age at follow-up was evaluated in 24 girls and 31 boys after 10 Gy single-fraction TBI, and 77 girls and 77 boys after 12–15.75 Gy fractionated-exposure TBI [52,112]. Following 10.0 Gy single-exposure TBI, 71% of girls and 83% of boys had delayed development of secondary sexual characteristics, elevated LH and FSH levels, and low sex hormone levels. After fractionated-exposure TBI, 49% of girls and 58% of boys had delayed development. The majority of these girls and boys have received appropriate sex hormone therapy for promotion of secondary sexual characteristic development.

The amount of testicular radiation received and patient age at the time of TBI are important factors in subsequent normal spontaneous pubertal development (Table 102.1). Thirty of the 36 (84%) boys who had received more than 10 Gy testicular irradiation for testicular leukemia in addition to 12–15.75 Gy TBI have primary gonadal failure and require testosterone therapy to promote the development of secondary sexual characteristics. However, about half of the boys who receive 400 cGy prophylactic testicular radiation in addition to fractionated TBI develop normally through

Table 102.1 Pubertal development in boys given testicular irradiation

		Testicular irradiation	
		4.0 Gy	**≥10 Gy**
Current age	≥12 years	51	36
Development	Normal	28 (55%)	6 (16%)
	Delayed	23 (45%)	30 (84%)

Data source: J.E. Sanders, unpublished data, 2007.

puberty (J.E. Sanders, unpublished data). Spermatogenesis can be impaired after 8 Gy, whereas Leydig cells are resistant to radiation doses up to 24 Gy [131].

Among children receiving 14.40 Gy fractionated TBI, one study reported that, among 17 boys evaluated, those with increased levels of LH were significantly younger at HCT (5.4 ± 0.8 versus 7.8 ± 0.8 years; $p = 0.024$), but among the 16 girls evaluated, those with ovarian failure were significantly older at the time of TBI than those with spontaneous puberty (8.6 ± 2.3 versus 6.1 ± 1.8 years; $p = 0.03$) [29]. Another study did not observe an effect of age on subsequent gonadal function [55]. A third analysis suggested that an effect of age may be linked to the total dose of TBI [125]. Among 30 evaluable children given 12.0 Gy TBI, 15 of 16 (94%) less than 10 years of age and 11 of 14 (78%) more than 10 years of age developed normally. However, among the 46 evaluable children given 14.40–15.75 Gy TBI, 23 of 30 (77%) less than 10 years of age and three of 16 (19%) more than 10 years of age developed normally. Larger numbers of patients are needed in order to be able to draw firm conclusions regarding the impact of patient age and total dose of TBI administered on the development of puberty.

It is recommended that the development of secondary sexual characteristics be monitored carefully after patients reach 10–11 years of age and that the Tanner stage of pubertal development be determined annually. Children with evidence of gonadal failure should be referred to a pediatric endocrinologist for consideration of sex hormone treatment. Patients with normal pubertal development, gonadotropins, and sex hormone production should receive appropriate sexual behavior counseling as pregnancy may occur.

Conclusion

Evaluations of endocrine function following HCT demonstrate that the occurrence of abnormalities that may influence subsequent growth and development are related to the type of HCT preparative regimen received. Children who receive CY only in their preparative regimen are at low risk for endocrine function abnormalities. These children typically have normal thyroid function, normal growth rates, and normal development through puberty. Individuals who develop normally through puberty or in whom gonadal function returns to normal may be fertile. Offspring of these patients, in general, do not differ from the general population.

Children who receive BU plus CY preparative regimens have normal thyroid function, and the majority have normal prepubertal growth rates although pubertal growth may be affected. Data from the patients evaluable for pubertal development suggest that a substantial proportion of these children may not develop secondary sexual characteristics at a normal age, which is particularly true for girls but not boys. Gonadal function, however, is likely to be abnormal in both boys and girls.

In contrast, HCT preparative regimens that contain TBI frequently result in multiple endocrine function abnormalities that affect normal growth and development. Patients are at risk for development of thyroid function abnormalities for many years after TBI, and also the risk for development of thyroid malignancy. Growth rates are usually blunted, especially if the child has received prior CNS irradiation. GH deficiency, which frequently occurs, and growth failure should be diagnosed and treated early with GH for the best response. Without GH treatment, young children have significantly compromised final adult heights. Gonadal damage results in a significant fraction of prepubertal patients having delayed pubertal development. Children with delayed development of secondary sexual characteristics may benefit from careful administration of appropriate sex hormone therapy. Children who do develop normally through puberty are potentially fertile.

All patients who receive HCT should continue to undergo long-term follow-up evaluations. Table 102.2 contains recommendations

Table 102.2 Selected screening recommendations for selected endocrine late effects after HCT in pediatric patients

Effect	Children's Oncology Group (COG) recommendations [133]	Joint Transplant Society recommendations [134]	Expert Panel recommendations [132]	
			Screening	Management
Thyroid dysfunction	Risks: XRT ≥10 Gy, thyroid in field. Yearly screening, more frequently during rapid growth	Thyroid function testing yearly post-HCT, or if relevant symptoms develop	TSH and FT4 annually: 1. for 10 years after busulfan; 2. for at least 30 years after TBI PE of thyroid yearly to screen for tumors after TBI	If TSH is high and FT4 normal, either treat or repeat in 2 months. Replace thyroid as indicated for low FT4 levels Rare secondary thyroid tumors post-TBI can be cured with surgery
Growth impairment	Risks – young age, TBI ≥10 Gy single fraction, ≥12 Gy fractionated. Screen with nutritional assessment, height/weight/BMI every 6 months until growth completed. Refer to endocrine for height <3rd percentile, drop ≥2 percentile rankings on growth chart, growth velocity <4–5 cm/year, lack of pubertal growth spurt	Pediatric recipients: monitor growth velocity in children annually; assessment of thyroid, and growth hormone function if clinically indicated	Accurate measure of growth yearly through full growth (age 17 years girls, 19 years boys). Bone age as needed	Bone age and referral to endocrine for patients not growing appropriately. GH therapy may unmask hypothyroidism
Reproductive risks	Risks: combined doses of alkylators, heavy metals, DTIC, temazolamide with XRT to cranium or gonads. Screen FSH/LH/testosterone, Tanner staging ages 13–14 and as clinically indicated for delayed puberty, irregular menses. Semen analysis, repeat as indicated as resumption can occur 10 years after therapy	Consider referral to appropriate specialists for patients who are contemplating a pregnancy or are having difficulty conceiving. Counsel sexually active patients in the reproductive age group about birth control post-HCT	Women: monitor ovarian function (FSH, estradiol, assess cycling). Men: testosterone, FSH, LH, semen analysis	Women: AMH may assess ovarian reserve. Treat ovarian failure with hormone replacement therapy. Men: if oligospermia noted, consider intracytoplasmic sperm injection

AMH, anti-Mullerian hormone; DTIC, dacarbazine; FT4, free thyroxine; PE, physical examination; TSH, thyroid-stimulating hormone; XRT, radiation therapy.
Recommendations from the Center for International Blood and Marrow Transplant Research (CIBMTR), the American Society of Blood and Marrow Transplantation (ASBMT), European Group for Blood and Marrow Transplantation (EBMT), Asia-Pacific Blood and Marrow Transplantation Group (APBMT), Bone Marrow Transplant Society of Australia and New Zealand (BMTSANZ), East Mediterranean Blood and Marrow Transplantation Group (EMBMT) and Sociedade Brasileira de Transplante de Medula Ossea (SBTMO) [132].

adapted from the Children's Oncology Group Long-Term Follow-up Guidelines, the Joint Transplant Society Recommendations published in 2012, and the consensus recommendations from an expert panel convened in 2011 from a National Cancer Institute (NCI), National Heart, Lung, and Blood Institute (NHLBI), and Pediatric Blood and Marrow Transplant Consortium (PBMTC)-sponsored consensus conference of international experts in clinical and biological research into late effects after HCT in children [132]. These recommendations form the basis for the comprehensive follow-up of thyroid function, growth, and development after HCT in children.

CHAPTER 103

Delayed Non-malignant Complications After Hematopoietic Cell Transplantation

Smita Bhatia
University of Alabama, Birmingham, AL, USA

Introduction

Over 70% of those who survive the first 2 years after hematopoietic cell transplantation (HCT) are now expected to become long-term survivors [1–3]. However, HCT survivors are at risk of developing a variety of long-term complications, such as endocrinopathies, musculoskeletal disorders, cardiopulmonary compromise, and subsequent malignant neoplasms (SMNs) (summarized in Table 103.1) [4–14]. These complications directly impact the burden of morbidity borne by HCT survivors, and have provided the rationale for standardized follow-up of HCT survivors at high risk for these complications. This chapter summarizes the magnitude of risk of key delayed non-malignant complications experienced by HCT survivors, identifying patients at increased risk because of host characteristics and therapeutic exposures. Some of these complications are described in greater detail elsewhere [gastrointestinal and hepatic complications (Chapter 94), lung injury (Chapter 95), kidney and bladder complications (Chapter 96), endocrine complications (Chapter 97), growth, development, and fertility issues (Chapter 102), and neurologic complications (Chapter 105)] and will therefore be summarized only briefly here, with reference to the relevant chapters where a detailed account on the specific issues can be found. Additionally, this chapter describes the overall burden of morbidity (physical and psychosocial) and the late mortality experienced by HCT survivors. Finally, it describes the current recommendations for follow-up, patterns of healthcare utilization by the HCT survivors, and adherence to these recommendations.

Cardiovascular risk factors and cardiac disease

HCT survivors are at risk for cardiovascular risk factors and also cardiovascular complications because of the combined effect of pre-HCT therapeutic exposures, transplant-related conditioning, and post-HCT graft versus host disease (GVHD). Furthermore, HCT recipients are at a 2.3–4.0-fold increased risk of death due to cardiac causes compared with the general population [1,10]. Late cardiotoxicity includes cardiomyopathy, congestive heart failure (CHF), valvular dysfunction, arrhythmia, and pericarditis. The association between anthracyclines and the subsequent development of cardiomyopathy is well established, and is primarily due to anthracycline-induced myocyte damage. Mediastinal radiation produces inflammation and fibrosis resulting in restrictive cardiomyopathy and valvular defects. Fibrosis also affects the electrical conduction pathways, causing arrhythmias. Late cardiovascular complications include the development of cerebrovascular disease and coronary artery disease after HCT [5,15–18], commonly reported together as cardiovascular disease (CVD), and often associated with pre-HCT cranial, neck, and mediastinal radiation.

Anthracycline-related cardiotoxicity is dose dependent and, in non-transplant patients, the incidence exceeds 25% in patients treated in the conventional setting with doses exceeding 550 mg/m^2 [19]. Among anthracycline-exposed childhood cancer survivors, female gender and younger age at exposure to anthracyclines and mediastinal radiation are known to increase the risk [20,21]. Evidence regarding the magnitude of risk of cardiovascular disease in HCT recipients is emerging. Risk factors unique to the HCT procedure that could potentially increase the risk of cardiomyopathy include conditioning with high-dose chemotherapy, total body irradiation (TBI), and GVHD. Furthermore, HCT survivors are at increased risk of de novo cardiovascular risk factors (CVRFs) such as diabetes, hypertension, and dyslipidemia due, in part, to exposure to TBI, immunosuppressive therapy, or other conditions such as growth hormone deficiency or hypothyroidism [5,22], and these could potentiate anthracycline-related cardiomyopathy

In a large cohort of autologous HCT recipients, the cumulative incidence of CHF was 9.1% at 15 years after HCT, and increased to 14.5% at 15 years [23]. The cohort was at a 4.5-fold increased risk compared with the general population. The risk increased substantially for patients receiving ≥250 mg/m^2 of cumulative anthracycline therapy [odds ratio (OR) 9.9, $p < 0.01$]. Presence of hypertension among recipients of high-dose anthracyclines (≥250 mg/m^2) resulted in a 35-fold increase in risk of CHF, and the risk was nearly 27-fold for high-dose anthracycline-exposed individuals with diabetes, providing evidence that hypertension and diabetes were critical modifiers of anthracycline-related myocardial injury after HCT. Pre-HCT exposure to anthracyclines in doses exceeding 250 mg/m^2 was also demonstrated to increase the risk of CHF in autologous and allogeneic HCT recipients [4]. In this study, anthracycline dose ≥250 mg/m^2 (OR 3.2, $p = 0.05$), number of pre-HCT chemotherapy cycles (OR 1.2, $p < 0.01$), and two or more comorbidities (OR 4.3, $p = 0.01$) were independently associated with late CHF.

CVD has emerged as a late complication after HCT, due in part to the more mature follow-up of the HCT survivors, allowing observation and reporting of complications with long latency.

Table 103.1 Commonly occurring long-term complications in survivors of hematopoietic cell transplantation

Adverse outcome	Therapeutic exposures associated with increased risk	Factors associated with highest risk
Cataracts	Cranial irradiation, TBI, steroids	Higher radiation dose, combination of steroids and radiation, single daily fraction
Cardiomyopathy/congestive heart failure	Pre-HCT anthracyclines	High cumulative doses, females, chest irradiation, post-HCT comorbidities (diabetes and hypertension)
Myocardial infarction	Pre-HCT radiation to chest	Underlying risk factors for coronary artery disease (smoking, hypertension, hyperlipidemia, obesity, etc.)
Pulmonary fibrosis/interstitial pneumonitis	Pre-HCT bleomycin, radiation to chest, carmustine, TBI, chronic GVHD	Younger age at treatment, bleomycin dose >400 U/m^2
Hypothyroidism	Pre-HCT radiation to the thyroid gland (neck, mantle, etc.), TBI	Increasing dose, female gender, older age at treatment
Hypogonadism	Pre-HCT alkylating agents, craniospinal irradiation, abdomino-pelvic irradiation, gonadal irradiation, TBI	Treatment during peripubertal or postpubertal period in girls, higher cumulative doses of alkylators
Renal insufficiency	Pre-HCT platinum-based therapy, ifosfamide, high-dose methotrexate, abdominal radiation, surgery, TBI, calcineurin inhibitors	High-dose chemotherapy, younger age, abdominal radiation and chemotherapy
Short stature	Pre-HCT cranial irradiation, corticosteroids, TBI	Younger age at treatment, cranial radiation dose >18 Gy, unfractionated (10 Gy) TBI
Osteopenia/osteoporosis	Pre-HCT craniospinal irradiation, gonadal irradiation, TBI, corticosteroids	Associated hypothyroidism, hypogonadism, growth hormone deficiency
Avascular necrosis	Corticosteroids, high-dose radiation to any bone, calcineurin inhibitors	Dexamethasone, adolescence, female gender

Late CVD following HCT has been classified as coronary artery disease [i.e. myocardial infarction, angina pectoris, or symptomatic atherosclerotic heart disease (coronary artery narrowing >50%)] or cerebrovascular disease [i.e. stroke, transient ischemic attacks, symptomatic lacunar infarct, or symptomatic carotid artery occlusion (>50% narrowing) necessitating surgical intervention], in accordance with the American College of Cardiology's established case definitions and clinical data standards for coronary artery and cerebrovascular disease. In the general population, increasing age, hypertension, diabetes, dyslipidemia, high body mass index (BMI), and male gender are known to modify the risk of CVD [24,25]. Among HCT survivors, the presence of multiple CVRFs (two or more of the following: obesity, dyslipidemia, hypertension, and diabetes) were associated with a 5.2-fold increased risk of late CVD ($p < 0.01$) [26]. Pre-HCT chest radiation was associated with a 9.5-fold greater risk of coronary artery disease ($p = 0.03$). Thus, pre-HCT exposure to chest radiation and the presence of comorbidities were primarily responsible for the risk associated with late CVD after HCT.

Several studies have demonstrated that HCT recipients are at an increased risk of CVRFs. A higher prevalence of self-reported diabetes and hypertension among HCT survivors compared with a sibling comparison group has been documented [5]. In a large cohort study, the 10-year cumulative incidence of hypertension, diabetes, and dyslipidemia was 37.7, 18.1, and 46.7%, respectively [27]. The prevalence of CVRFs was significantly higher among HCT recipients than the general population, contributed to largely by allogeneic HCT recipients. Older age and obesity at HCT were associated with an increased risk of CVRFs. History of grade 2–4 acute GVHD was associated with an increased risk of hypertension [relative risk (RR) 9.1, $p < 0.01$], diabetes (RR 5.8, $p < 0.01$), and dyslipidemia (RR 3.2, $p < 0.01$); conditioning with TBI was associated with an increased risk of diabetes (RR 1.5, $p = 0.01$) and dyslipidemia (RR 1.4, $p < 0.01$). Most importantly, this study demonstrated that the high incidence of CVRFs in HCT survivors was directly responsible for the subsequent development of CHF and CVD. Thus, the 10-year cumulative incidence of CHF and CVD increased with the number of CVRFs present in the patients prior to the diagnosis of CHF or CVD (no CVRFs, 4.7%; 1 CVRF, 7.0%; ≥2 CVRFs, 11.2%, $p < 0.01$). The risk was especially high (15%) for patients with multiple CVRFs and pre-HCT exposure to anthracyclines and chest irradiation.

These studies demonstrate that the risk of CHF and CVD is increased after HCT, and is related primarily to pre-HCT exposure to anthracyclines (CHF) or chest irradiation (coronary artery disease). Furthermore, the risk of CVRFs is increased after HCT, especially among older individuals exposed to TBI and among those who develop acute GVHD. Finally, the risk of anthracycline-related CHF or chest irradiation-related coronary artery disease is increased substantially among patients with one or more CVRFs. These data form the foundation for identifying high-risk individuals who should undergo targeted surveillance, in addition to providing a rationale for interventional strategies in the form of aggressive management of CVRFs.

Recommendations for screening

Patients exposed to anthracyclines should undergo monitoring for late-onset cardiomyopathy using serial non-invasive testing (echocardiogram) and physical examination. The intensity of echocardiographic screening can range from annual to every 5 years, depending on cumulative anthracycline dose, age at exposure, treatment with mediastinal radiation, and presence of CVRFs. Survivors who received radiation involving the heart field should also be monitored for early-onset atherosclerosis. Lifestyles that promote good heart health should be recommended to all survivors, including smoking cessation, a regular exercise program, dietary recommendations, and screening for (and aggressive management of) dyslipidemia, hypertension, and diabetes.

Delayed pulmonary complications

Delayed pulmonary complications are frequent after HCT, and typically include infectious complications related to the compromised immune system and non-infectious complications. Non-infectious pulmonary complications include the following: bronchiolitis obliterans (BO), bronchiolitis obliterans organizing pneumonia (BOOP), and idiopathic pneumonia syndrome (IPS) [28]. A detailed account of lung injury after HCT can be found in Chapter 95.

Non-infectious complications usually appear 3 months to 2 years after HCT, and are closely related to chronic GVHD. However, the functional consequences persist for years. The cumulative incidence of non-infectious pulmonary complications approaches 10% at 2 years after HCT [29]. Both the magnitude and severity of non-infectious pulmonary complications are worse after unrelated donor HCT. The cumulative incidence is 15.6% among those diagnosed with chronic GVHD. The overall survival at 5 years is significantly inferior among those with pulmonary complications compared with those without.

BO is characterized by a non-specific inflammatory injury affecting the small airways, with an incidence approaching 8% [30]. BO is strongly associated with chronic GVHD; additional factors associated with increased risk include use of peripheral blood stem cells, exposure to methotrexate for GVHD prophylaxis, older age of the recipient and/or donor at HCT, exposure to busulfan for conditioning, prior history of respiratory infection, and low serum immunoglobulin levels. The onset of BO is protracted, and typically occurs approximately 1 year after HCT. Manifesting as an obstructive defect in the initial stages, it progresses to peribronchiolar fibrosis, with emergence of restrictive changes [31]. Patients present with a dry cough, progressive dyspnea, and wheezing. High-resolution computed tomography (CT) images of the chest in inspiration and expiration are considered to be the radiologic procedure of choice to measure the structural alterations in the lung. A characteristic finding in patients with BO is a mosaic image, and carries a sensitivity of 74–91% and a specificity of 67–94% [32]. Criteria used to make a clinical diagnosis of BO include (i) $FEV_1/FVC < 0.7$ and FEV_1 <75% of predicted value, (ii) evidence of air trapping or small airway thickening or bronchiectasis on high-resolution CT, and (iii) absence of respiratory infection [33].

BOOP is a clinicopathologic syndrome involving bronchioles, alveolar ducts, and alveoli. The syndrome has a cumulative incidence of less than 2%. It typically presents as an interstitial pneumonia and usually occurs within the first 12 months following HCT. The clinical presentation in patients is acute, with the sudden onset of a dry cough, and also dyspnea and fever. Pulmonary function tests suggest a restrictive pattern and observations from chest X-ray show peripheral patchy consolidation, ground-glass attenuation and nodular opacities [34]. Definitive diagnosis requires histologic confirmation. Patients with BOOP are more likely to have acute or chronic GVHD.

IPS usually occurs within the first 4 months after HCT; risk factors include exposure to TBI and pre-HCT pulmonary-toxic chemotherapy and the presence of GVHD, with the risk increasing with age at HCT [35]. Late-onset interstitial pneumonitis occurs years after HCT, typically in patients with severe chronic GVHD of the sclerodermatous cutaneous variety. A restrictive defect is found on pulmonary function tests [36].

Recommendations for screening

Monitoring for pulmonary dysfunction in HCT survivors should include the assessment of symptoms such as chronic cough or dyspnea. Patients should be counseled about the risks of smoking and exposure to second-hand smoke. It is recommended that pulmonary function tests and chest X-rays are carried out upon entry into long-term follow-up for at-risk patients, and should be repeated as clinically indicated in symptomatic patients and in those with subclinical abnormalities identified at screening. Influenza and pneumococcal vaccines are recommended in survivors at risk for pulmonary compromise.

Endocrine complications

Endocrine complications are among the most common chronic health conditions encountered after HCT, and include thyroid dysfunction, osteoporosis, growth impairment, and gonadal dysfunction. The risk of these complications is influenced by pre-HCT therapeutic exposures, transplantation-related conditioning, and post-transplantation management of GVHD. Endocrinopathies and their consequences are described in greater detail in Chapters 97 and 102.

Thyroid abnormalities primarily include subclinical and overt hypothyroidism. Subclinical or compensated hypothyroidism is defined as elevated thyroid-stimulating hormone (TSH) accompanied with normal T4 levels. The incidence of compensated hypothyroidism ranges from 25 to 30%, with a median latency of 2 years. Overt hypothyroidism is characterized by low T4 levels accompanied by elevated TSH; the cumulative incidence ranges from 3.4 to 9% with a latency of 2.7 years. Hypothyroidism is directly related to radiation to the thyroid gland (either as part of neck/mediastinal radiation or TBI). Younger age at exposure to radiation increases the risk [37,38].

HCT recipients are at risk for osteopenia and osteoporosis. The decreased bone mineral density is due to the use of steroids in the treatment of GVHD [39], growth hormone deficiency [40], hypogonadism [41,42], physical inactivity, and a diet low in calcium [43]. The incidence of osteopenia in adults is reported to approach 50% at 4–6 years after HCT, while the incidence of osteoporosis approaches 20% at 2 years [44–49]. The average decrease in bone mineral density (BMD) has been reported to be 6–10% in the femoral neck region and 2–6% in the lumbar region, and the most significant loss in BMD occurs during the first 6 months after HCT [48–50]. Spine and total body BMD have been shown to return to baseline at month 48 [42]. Bone mineral loss increases the risk of fractures in the HCT population, as it does in the general population. Non-traumatic fractures have been observed in 10.6% of the population within 3 years after HCT [44].

Growth impairment is a frequent complication in children after HCT [49]. While central damage to the hypothalamic–pituitary axis due to cranial radiation or TBI is the primary mediator, several factors modify the risk, including nutritional and hormonal (gonadal failure, hypothyroidism) factors, exposure to corticosteroids for the management of GVHD, and peripheral lesions of the bones, cartilage, and epiphyseal growth plate [50]. Short stature after exposure to TBI could be due to the impairment of growth directly, by damaging epiphyseal growth plates, or indirectly, by decreasing growth hormone secretion, or by causing hypogonadism or hypothyroidism. The final height standard deviation (SD) score of the patient conditioned with TBI is significantly lower than that of the patient conditioned without TBI [51].The loss of height is more severe in boys than girls. Patient age at exposure to TBI is a significant factor in predicting adult height. Children younger than 10 years of age at HCT are at greatest risk for short stature [52]. Patients conditioned with chemotherapy alone attain final height values within predicted ranges. The final height in patients treated with hyperfractionated TBI is similar to that in patients receiving standard fractionation; however, the reduction in height in this group is due to a reduction in sitting height, suggesting impairment of spinal column growth [50]. Growth hormone insufficiency is the leading cause of growth impairment – the prevalence ranges from 20 to 85%. Maximum benefit to final height is achieved with growth hormone replacement for patients with documented growth hormone deficiency who were transplanted before 10 years of age [53].

Gonadal failure is a frequent endocrine complication after HCT. Pubertal disturbances after HCT are caused by radiation-related perturbations of the hypothalamic–pituitary axis and/or by chemoradiotherapy-related damage to the gonads. Testicular germinal epithelium (Sertoli cells) is responsible for spermatogenesis and is more sensitive to radiation and chemotherapy than the testicular Leydig cell component, which is involved in testosterone secretion. The probability of developing gonadal failure increases with cumulative doses of gonadotoxic therapies. Recovery of spermatogenesis seems to occur more frequently in patients receiving lower doses of cyclophosphamide (120 mg/kg) than in those treated with higher doses (200 mg/kg). Males who are long-term survivors have a considerable chance of recovering some degree of sperm production even when treated with TBI, provided that they are under 25 years of age at HCT and do not develop chronic GVHD [54,55].

Ovaries are more vulnerable to radiation and chemotherapy. It has been shown that whereas approximately 50% of prepubertal girls who receive fractionated TBI enter puberty spontaneously and achieve menarche at a normal age, almost all female patients who are more than 12 years old when undergoing HCT show ovarian failure, probably as a result of decreased reserve of primordial follicles [56]. High-dose busulfan is a significant cause of ovarian failure even when it is administered in the prepubertal period [57]. Irreversibility of ovarian function after HCT in most patients highlights the necessity for timely hormonal replacement therapy to prevent osteoporosis and other complications resulting from lack of hormones.

Recommendations for screening

Thyroid

Screening for thyroid dysfunction relies on a good history and physical examination, and also annual thyroid function tests (free thyroxine, thyroid-stimulating hormone). Survivors with abnormalities on screening evaluation should be referred to an endocrinologist for hormone replacement therapy.

Growth

Growth and growth velocity should be measured every 6 months during childhood. Any deviation from the SD score from age- and gender-expected means should prompt a consultation with the endocrinologist.

Gonadal function

For males, screening for hypogonadism should include an age-appropriate history and physical examination, with attention to issues related to libido, impotence, or fertility. Measurement of serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone levels has been recommended as a baseline at age 11 years and in boys whose puberty appears to be delayed. Abnormalities in testicular function should prompt a consultation with the endocrinologist. For fmales, screening for ovarian dysfunction involves history (primary or secondary amenorrhea, menstrual irregularity, and pregnancies or difficulties in becoming pregnant), physical examination, and serum gonadotropin and estradiol levels. For patients with absence of clinical evidence of puberty, baseline studies should be obtained at the expected time of onset of puberty to assess the need for hormone therapy to induce puberty.

Fertility

Permanent gonadal damage and infertility are known toxicities of preparative regimens used for patients undergoing HCT [13,58–60]. HCT survivors were found to be 36 times more likely to not report a conception compared with age- and gender-matched siblings [61]. Older age at transplantation (≥30 years: OR 4.8), female gender (OR 3.0), and exposure to TBI (OR 3.3) are associated with increased risk for infertility. Infertility should be regarded as a complication of significant concern as it has the potential to influence various medical and quality of life (QOL) aspects of survivorship. In fact, some survivors have reported that the potential loss of fertility was as painful as confronting cancer [62,63]. Survivors under the age of 40 years and those without children before HCT express significantly elevated infertility concerns [64]. Although HCT survivors are at an extremely high risk for infertility secondary to gonadotoxic myeloablative therapy, survivor fertility status cannot be definitely known without testing.

The high prevalence of infertility, and the high rate of infertility-related concerns among cancer survivors, increase the need for transplanters to discuss fertility-preserving options prior to HCT with prospective HCT recipients, and for healthcare providers taking care of long-term HCT survivors to provide family-building options and psychosocial support to those at risk.

Osteonecrosis

Osteonecrosis is a debilitating and painful condition that develops when the blood supply to the bone is compromised, usually in areas with terminal circulation. Osteonecrosis has been reported as a complication of HCT, and can cause significant morbidity and often requires surgery. The cumulative incidence reported in the literature has ranged from 3 to 10% at 5 years after HCT [65–67]. The risk of osteonecrosis is highest among unrelated donor recipients, approaching 15% at 10 years after HCT (Figure 103.1) [68]. Risk factors for osteonecrosis include GVHD therapy with corticosteroids or calcineurin inhibitors and the use of TBI for conditioning [65,66,69]. Among recipients of allogeneic HCT, males (RR 2.1), those with chronic GVHD (RR 2.2), and those exposed to three of the four drugs cyclosporine, FK506, prednisone, and MMF (RR 9.2) are at increased risk [68]. The association with corticosteroids increases with increasing dose. When compared with no corticosteroid exposure, exposure to 1–3869 mg of prednisone was found to be associated with a 4.0-fold increased risk of osteonecrosis, exposure to 3870–9735 mg with a 5.6-fold increased risk, and exposure of >9735 mg with an 8.6-fold increased risk [70]. Pathogenesis of osteonecrosis includes local vascular damage that leads to

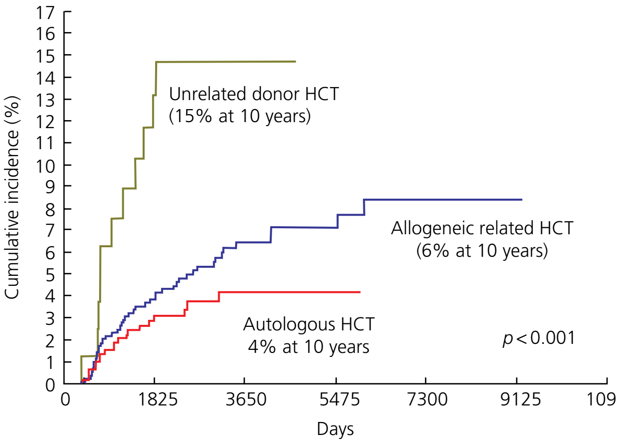

Figure 103.1 Cumulative incidence of avascular necrosis by type of HCT. Source: adapted from Campbell et al. 2009 [68].

increased marrow edema and ischemia, ineffective osteoblastic repair processes due to metabolic factors, and mechanical stresses [71]. The femoral head is the most commonly affected area; others include the knee and shoulder joints.

Recommendations for screening

Clinical anticipation in at-risk survivors guiding a careful history and a thorough physical examination are the cornerstone of screening. Prompt radiologic screening with appropriate interventions can reduce the morbidity related to pain and lack of mobility.

Chronic kidney disease

Renal dysfunction has long been recognized as a complication of HCT [72–79], and is detailed in Chapter 96. Conventionally, chronic kidney disease is defined as a persistently (≥3 consecutive months) low glomerular filtration rate (GFR) of <60 mL/min/1.73 m^2. However, direct measurement of GFR is logistically difficult in routine clinical practice, and has therefore precluded reports on chronic kidney disease with large samples. This limitation was overcome in a study by applying the endogenous filtration marker creatinine to assess GFR, in the Modification of Diet in Renal Disease (MDRD) Study equation endorsed by the National Kidney Foundation [7]. Using this definition, the cumulative incidence of chronic kidney disease was found to approach 4.4% at 5 years for the entire cohort; the cumulative incidence was 3.8% among autologous HCT recipients, 4.5% for matched sibling HCT recipients, and 10% for unrelated donor HCT recipients. For every 5-year increment in age at HCT, the risk of chronic kidney disease increased by 33%. In addition, exposure to cyclosporine without tacrolimus (RR 1.9) or with tacrolimus (RR 4.6) and a primary diagnosis of multiple myeloma (RR 2.5) were associated with an increased risk of delayed chronic kidney disease. Older patients exposed to calcineurin inhibitors were at the highest risk (Figure 103.2).

Recommendations for screening

Patients at risk for chronic kidney disease should be monitored with evaluation of serum creatinine, blood urea nitrogen, and serum chemistries at entry into long-term follow-up; these tests should be repeated as clinically indicated. Urinalysis and measurement of blood pressure should be performed at baseline and annually thereafter. Patients at risk for chronic kidney disease should be cautioned to avoid nephrotoxic agents (e.g. ibuprofen, aminoglycosides) and to seek early intervention for urinary tract infections.

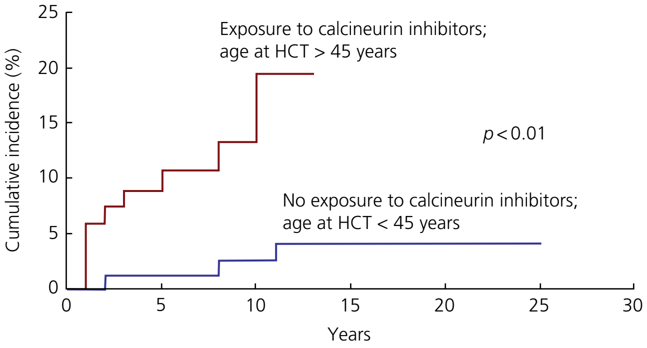

Figure 103.2 Cumulative incidence of chronic kidney disease by age at exposure to calcineurin inhibitors among allogeneic HCT recipients. Source: adapted from Choi et al. 2008 [7].

Visual impairments

The association between cataract formation and exposure to ionizing radiation has been recognized since the late 19th century. Following HCT, it is well known that TBI-based conditioning regimens are more cataractogenic [80–82]. The major risk factors for development of cataracts include TBI (including total dose, fractionation, or dose rate) [80,83–86] and pre-HCT cranial irradiation [81,84].

The cumulative incidence of cataracts approaches 36% at 15 years after HCT performed in childhood [87]. Data from the European Bone Marrow Transplant Registry [88] that included adults demonstrated the overall 10-year estimated cataract incidence to be 50%. It was 60% in the patients who had received single-dose TBI, 43% among those who had received six or fewer fractions, and 7% among those who had received more than six fractions. Furthermore, the cumulative incidence of cataracts was significantly lower (30%) among patients who had received a low dose rate of radiation (≤0.04 Gy/min) compared with those who had received a high dose rate (>0.04 Gy/min) (59%). Patients who had received heparin for prophylaxis against venocclusive disease had fewer cataracts (cumulative incidence 33% versus 53%). Multivariate analysis revealed older age (>23 years), higher dose rate, allogeneic HCT, and steroid administration (>100 days) to be associated with an increased risk of cataract formation.

Recommendations for screening

Patients at risk for cataracts should undergo annual fundoscopic examination and assessment for visual acuity. Surgical interventions (cataract extraction, photocoagulation) may be indicated, with preservation of the sight being the overall goal.

Chronic disease burden after hematopoietic cell transplantation

As described above, HCT survivors are at risk for developing a variety of long-term complications. Most studies conventionally focus on individual complications, providing insight into their etiology and pathogenesis and identifying patients at increased risk, so that targeted surveillance and interventions can be instituted to reduce morbidity and mortality. However, the burden of morbidity resulting from the cumulative impact of these individual complications needs to be examined, so that care can be tailored accordingly. Health problems experienced by 10-year survivors of HCT have been documented by Syrjala et al. [89]. Survivors reported twice as many medical problems when compared with controls ($p < 0.001$). Survivors were more likely to report musculoskeletal symptoms, cataract surgery, liver problems, sexual problems, memory and attention concerns ($p = 0.003$), urinary symptoms, and use of psychotropic medication. In another study, investigators described the risk of chronic health conditions in HCT survivors and siblings [90]. The Common Terminology Criteria for Adverse Events, Version 3.0, was used to assign severity score [grades 1 (mild) through 4 (life-threatening)] to each health condition. Two-thirds of the HCT survivors and 39% of the siblings developed at least one chronic health condition ($p < 0.0010$). Whereas one-fifth of the HCT survivors developed severe/life-threatening conditions, only 8% of the siblings did so ($p < 0.001$). The cumulative incidence of a chronic health condition was 59% at 10 years after HCT; for severe/life-threatening conditions, the 10-year cumulative incidence approached 35% (Figure 103.3). HCT survivors were 3.5 times more likely to develop severe/life-threatening conditions than the siblings, and HCT survivors with chronic GVHD were

4.7 times more likely. HCT survivors were more likely to report gastrointestinal, musculoskeletal, and cardiovascular problems compared with an age-, gender- and race-adjusted sibling group.

The burden of morbidity reported after HCT represents the cumulative toxicities resulting from exposure to pre-HCT chemotherapy and radiation, transplantation-related conditioning regimens, post-HCT GVHD, and medications used to manage acute and chronic GVHD, and the development of comorbidities after HCT. The long-term morbidity ascribed to the HCT procedure was examined recently [91]. In this study, the investigators compared the risk of chronic health conditions and adverse health in survivors of HCT performed in childhood with survivors of childhood cancer treated conventionally. About 25% of the HCT survivors reported severe/life threatening conditions. HCT survivors were 3.9 times more likely to report severe/life-threatening conditions ($p < 0.01$) than conventionally treated patients. Furthermore, they were 3.5 times more likely ($p <0.01$) to report functional impairment and 5.8 times more likely ($p < 0.01$) to report activity limitation than conventionally treated patients. Unrelated donor HCT recipients were at the highest risk. Understanding the burden of morbidity after HCT is important for a variety of reasons. It is important to the healthcare providers and policy makers in identifying and procuring resources for the long-term care of persons with a high burden of morbidity, to the researchers in identifying common etiologic pathways that increase the risk of overall morbidity, and to the HCT survivors in making informed decisions regarding the QOL concerns long-term after HCT.

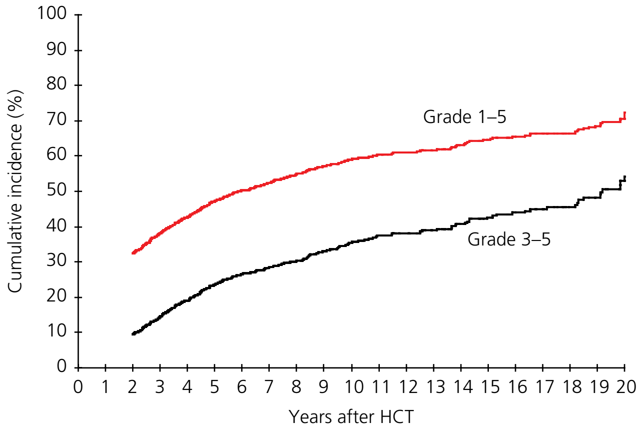

Figure 103.3 Cumulative incidence of any chronic health conditions (grades 1–5) and severe or life-threatening chronic health conditions (grade 3 or 4) or death due to a chronic health condition (grade 5) after HCT. Source: adapted from Sun et al. 2010 [90].

Late mortality

The high burden of morbidity carried by HCT recipients can result in premature death. Several studies have examined late mortality in patients undergoing HCT, and these are summarized here.

Late mortality experience was evaluated in a cohort of autologous HCT recipients who had survived 2 years or longer after HCT for hematologic malignancies [2]. Overall survival was 68.8% at 10 years (Figure 103.4a), and the cohort was at a 13-fold increased risk for premature death compared with the general population. Relapse

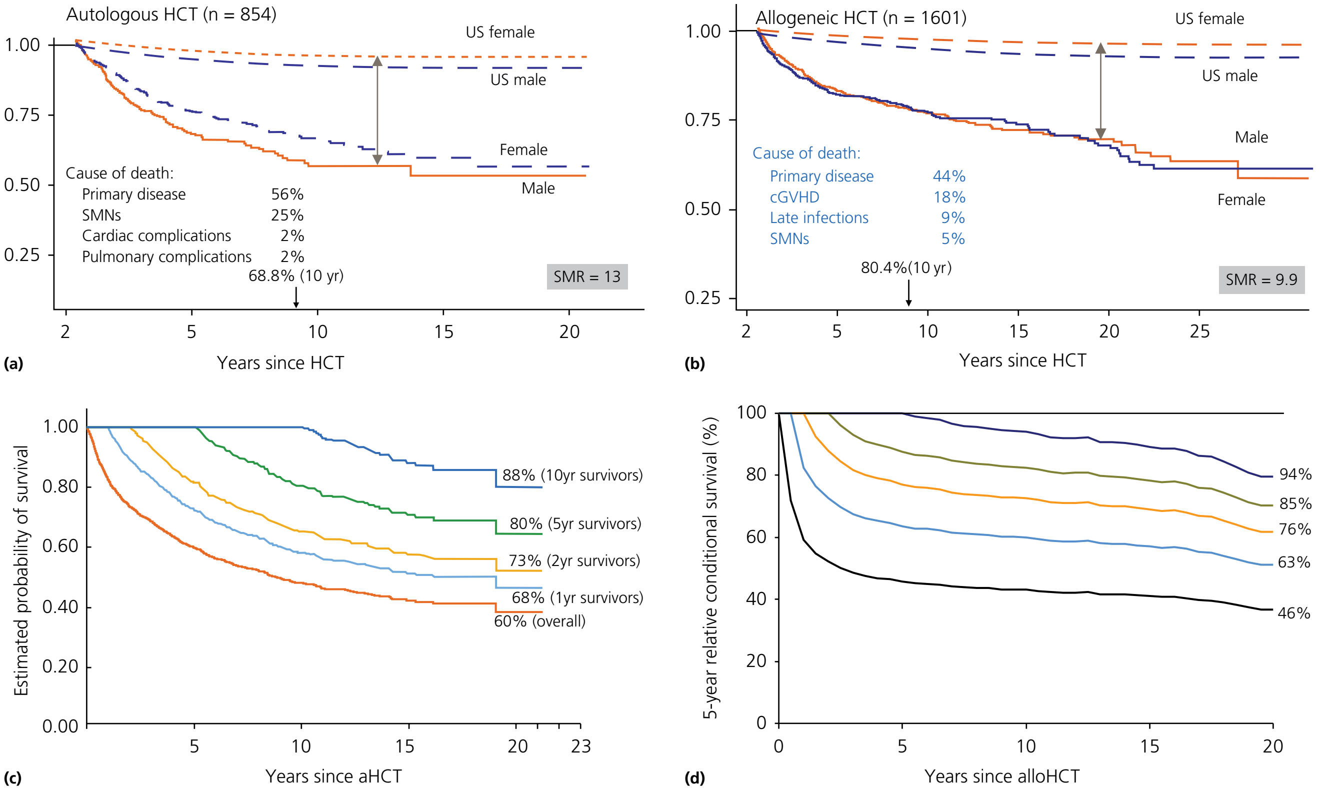

Figure 103.4 (a) Late mortality after autologous HCT. Source: adapted from Bhatia et al. 2005 [2]. (b) Late mortality after allogeneic HCT. Source: adapted from Bhatia et al. 2007 [1]. (c) Conditional cause-specific survival after autologous HCT. Source: adapted from VanderWalde et al. 2013 [94]. (d) Conditional cause-specific survival after allogeneic HCT. Source: adapted from Armenian et al. 2012 [95].

of primary disease (56%) and SMNs (25%) were leading causes of premature death. Compared with patients with AML, relapse-related mortality was increased among patients with Hodgkin lymphoma (RR 3.6), non-Hodgkin lymphoma (RR 2.1), and acute lymphoblastic leukemia (RR 6.5). TBI provided a protective effect (RR 0.6). Non-relapse-related mortality was increased after carmustine (RR 2.3) and with use of peripheral blood stem cells (RR 2.4). Subsequent malignancies accounted for a 12-fold higher mortality rate than that expected in the general population, pulmonary dysfunction 5.6-fold, and cardiac compromise 4.4-fold.

Late mortality experience was also evaluated in individuals who had survived 2 years or longer after allogeneic HCT [1]. It was demonstrated that the survival probability at 15 years after HCT was 80.2% for those individuals who had survived 2 years after HCT (Figure 103.4b), with a relative mortality of 9.9. Relapse of primary disease (29%) and chronic GVHD (22%) were the main causes of premature death. Non-relapse-related mortality was greater among patients who were over 18 years of age when undergoing HCT, and also among those with chronic GVHD (RR 2.7), and was reduced among individuals who received methotrexate for GVHD prophylaxis (RR 0.5). Compared with the general population, allogeneic HCT recipients were 15.1 times more likely to have died of a pulmonary dysfunction, 3.6 times more likely to have died of a subsequent new malignancy, and 3.6 times more likely to have died of cardiac compromise. In another cohort of allogeneic HCT recipients who had survived 2 years or longer after HCT, the probability of being alive 10 years after HCT approached 85% [92]. Relapse was the major cause of death; the major cause for non-relapse-related mortality was GVHD.

In a recent cohort study of patients who had survived for at least 5 years after allogeneic or autologous HCT without recurrence of the original disease, the estimated survival of the cohort at 20 years of follow-up after HCT was 80.4% [93]. Mortality rates were 4–9-fold higher than in the general population for at least 30 years following HCT, producing an estimated life expectancy that was 30% lower compared with normal subjects, regardless of current age. Leading causes of excess deaths were SMNs and recurrent diseases, followed by infections, chronic GVHD, and respiratory and cardiovascular disease.

The probability of survival is conventionally calculated from the date of HCT, despite the fact that the probability of survival changes for patients who have survived for a specified length of time after transplantation. Conditional survival is the survival probability of a cohort that takes into consideration the fact that the cohort has already survived a given length of time. The hazard of mortality changes with time from HCT, since the risk of relapse decreases, while the risk of chronic health conditions increases – but these occur at different rates. The concept of "conditional probability" takes into account that hazard rates change in a measurable way over time. Conditional survival applies this concept to determine the probability that a patient who has survived for a designated period will be alive at another fixed interval. A recent study determined disease- and cause-specific conditional survival for autologous HCT recipients [94] (Figure 103.4c). Estimated probability of relative survival was 62% at 5 years and 50% at 10 years from autologous HCT. On the other hand, 5-year relative survival was 70, 75, 81, and 88% after having survived 1, 2, 5, and 10 years after HCT, respectively. The risk of death approached that of the general population for 10-year survivors [standardized mortality ratio (SMR) 1.4, 95% confidence interval (CI) 0.9–1.9], with the exception of female Hodgkin lymphoma patients transplanted before 1995 at age 40 years or younger; these individuals were at a sixfold increased risk of premature death compared with the general population. Among those who had survived 10 years, non-relapse-related mortality rates exceeded relapse-related mortality rates. Cause-specific conditional survival in allogeneic HCT recipients was also examined [95] (Figure 103.4d). Conventionally computed probability of survival was 44.6% at 5 years and 41.2% at 10 years from allogeneic HCT. On the other hand, conditional 5-year survival rates at 6 months and 1, 2, and 5 years after allogeneic HCT were 62, 75, 83, and 93%, respectively. Among patients followed for 15 years or longer after allogeneic HCT, the risk of all-cause mortality was 2.6-fold that of the general population. Individuals who survived the first 5 years had negligible (≤5%) risk of relapse- and GVHD-related mortality over the subsequent 5 years. On the other hand treatment-related mortality increased over time; among those who survived the first 5 years, treatment-related mortality rates exceeded relapse-related mortality.

In summary, patients who have survived for 2–5 years after HCT without recurrence of the original disease have a high probability of surviving an additional 15 years. However, life expectancy is not fully restored to the level seen in the normal population in most patients, although the cause of death shifts from disease-related to treatment-related with increasing time after HCT.

Health behaviors of long-term survivors of hematopoietic cell transplantation

The high burden of morbidity borne by HCT survivors necessitates that they engage in health promotion, prevention, and screening behaviors after HCT. A recent study examining health behaviors and cancer screening practices [96] found that HCT survivors were more likely to have received a mammogram (OR 2.8, $p = 0.05$) than their siblings. Furthermore, HCT survivors were less likely to indulge in high-risk behavior (OR 0.5, $p < 0.01$) than their siblings. In the analysis restricted to HCT survivors, patients younger than 35 years at study participation (OR 4.7, $p < 0.01$) and those with lower education (below college level: OR 2.1, $p < 0.01$) were more likely to demonstrate high-risk behavior. Another study confirmed these findings, demonstrating that HCT survivors had similar health and screening behaviors to matched controls [97].

In summary, HCT survivors had comparable cervical and testicular cancer screening practices, were more likely to have had breast cancer screening by mammography, and were less likely to be engaged in high-risk behaviors compared with healthy controls. However, despite potential long-term risks, certain subsets of survivors continue to engage in high-risk behaviors such as smoking and excessive alcohol intake, indicating the need for targeted interventions for these high-risk populations. Continued vigilance in encouraging appropriate cancer screening and healthy behaviors for HCT survivors is critical.

Quality of life after hematopoietic cell transplantation

The psychologic health of HCT survivors has been evaluated by several investigators, using both cross-sectional and longitudinal study designs. Adverse psychologic outcomes in long-term HCT survivors were evaluated using a healthy comparison group composed of siblings [98]. Psychologic health status was evaluated using the Brief Symptom Inventory-18. About 22% of the HCT survivors reported adverse psychologic outcomes, compared with 8% of siblings ($p < 0.01$); 15% of HCT survivors reported somatic distress, representing an almost threefold higher risk compared with siblings. Among survivors, exposure to prednisone was associated with psychologic distress across all domains (anxiety, depression, and somatic distress). In addition, low annual household income and self-reported poor health, having severe/life-threatening chronic health conditions, and the presence of active chronic GVHD were associated with a twofold increased risk for somatic distress. Of HCT survivors, 7% expressed suicidal ideation; patients with higher scores on depression subscale were most vulnerable.

In addition to cross-sectional studies describing long-term psychologic wellbeing, investigators have utilized a prospective longitudinal study design to determine the trajectory of QOL from before HCT to several years after. Physical, psychologic, social, and spiritual wellbeing were assessed before HCT and at 6 months and 1, 2, and 3 years after HCT [99]. For all HCT patients, physical QOL was stable from before to after HCT, and psychologic, social, and spiritual wellbeing improved at 6 months. Allogeneic HCT recipients reported worse physical and psychologic wellbeing. Older patients reported worse physical but better social wellbeing regardless of HCT type. Two or more domains were affected by race/ethnicity, household income, and education in autologous HCT recipients; and by BMI, decline in BMI, primary diagnosis, and chronic GVHD in allogeneic HCT recipients. At 3 years, 74% of HCT recipients were employed full or part time. Older autologous HCT recipients with lower pre-HCT income were less likely to return to work; among allogeneic HCT recipients, patients with chronic GVHD were less likely to return work.

In another prospective longitudinal study, function was assessed from pre-HCT to 5 years post-HCT for adults who had received myeloablative HCT for leukemia or lymphoma [100]. The investigators studied physical limitations, return to work, depression, and distress before transplantation, at 90 days and 1, 3, and 5 years after HCT. It was found that physical recovery occurred earlier than psychologic recovery or return to work. Only 19% recovered with respect to all outcomes at 1 year. The proportion without major limitations increased to 63% at 5 years. Among survivors in complete remission, 84% returned to full-time work by 5 years. Patients with chronic GVHD ($p = 0.01$), those with less social support before HCT ($p = 0.001$), and women ($p < 0.001$) were more depressed after transplantation. Transplant-related distress was slower to recover for allogeneic HCT recipients and those with less social support before HCT ($p < 0.01$).

Sexual wellbeing is an important component of QOL, and information regarding the longitudinal trajectory of sexual wellbeing in HCT cohorts is emerging. The prevalence and predictors of sexual dysfunction in adult HCT recipients were assessed pre-HCT and at 1 and 3 years after [101]. Men and women did not differ in sexual satisfaction prior to transplantation. At 1 and 3 years post-HCT, women reported significantly more sexual dysfunction than men; 80% of the female participants and 29% of the male participants reported at least one sexual problem by 3 years after HCT. Among men, older age at HCT, poorer psychologic functioning prior to HCT, not being married, and lower sexual satisfaction prior to HCT predicted sexual dissatisfaction at 3 years after HCT. On the other hand, among women, lack of receipt of hormone replacement therapy and less sexual satisfaction at 1 year after HCT were associated with sexual dissatisfaction at 3 years post-HCT.

A second study delineated the trajectory of sexual wellbeing from before HCT to 3 years after in allogeneic and autologous HCT recipients and identified predictors of diminished sexual functions [102]. The participants completed the Derogatis Interview for Sexual Function Self Report and the Derogatis Global Sexual Satisfaction Index prior to HCT and at 6 months and 1, 2, and 3 years post-HCT. It was found that two-thirds of men were sexually active at the pre-HCT time point, declining to 51% at 3 years post-HCT ($p = 0.01$). On the other hand, one-third of women were sexually active at the pre-HCT time point, increasing to 48% at 3 years post-HCT ($p = 0.02$). Both men and women experienced a significant and persistent decline in sexual satisfaction after transplantation ($p < 0.001$). Among men, the sexual functioning scores for the Orgasm ($p = 0.002$) and Drive/Relationship ($p < 0.001$) domains declined after HCT, whereas among women, the scores for the Cognition/Fantasy ($p = 0.01$) and Behavior/Experience domains ($p = 0.01$) improved. Despite these gender-specific longitudinal trends, sexual function was worse in women than in men at all times and across all domains ($p \leq 0.001$). Older age negatively impacted sexual function in both men and women after HCT ($p < 0.01$). Chronic GVHD was associated with lower scores for the Cognition/Fantasy ($p = 0.003$) and Orgasm ($p = 0.006$) domains in men and the Arousal domain ($p = 0.05$) and sexual satisfaction ($p = 0.005$) in women. Finally, men exposed to TBI experienced a significant decline in sexual function across all domains ($p < 0.05$).

These studies demonstrate the gender-specific sexual concerns after HCT, and the need for a multidisciplinary approach to intervention in the vulnerable subpopulations.

Neuropsychologic wellbeing

Impaired cognition is an increasingly recognized consequence in HCT survivors, with the potential to impact societal reintegration, such as return to work. Decline in memory, learning, attention, concentration, and psychomotor and executive functioning have been reported after HCT. Neurotoxic agents (cranial and total body irradiation; high-dose chemotherapy, intrathecal methotrexate, and steroids) place HCT survivors at risk for cognitive impairment. Utilizing a prospective longitudinal study design [103], allogeneic HCT recipients completed standardized neuropsychologic tests including information processing speed, verbal memory, executive function, and motor dexterity and speed after 80 days and 1 and 5 years after HCT. Case-matched control subjects received testing at the 5-year time point. It was demonstrated that survivors recovered significant cognitive function from the 80-day time point to 5 years in all tests ($p < 0.001$) except verbal recall. Between 1 and 5 years, improvements were noted in verbal fluency ($p = 0.0002$) and executive function ($p < 0.01$). However, motor dexterity did not improve, remaining more than 0.5 SD below population norms. Using the Global Deficit Score as a summary of overall impairment, 41.5% of the survivors and 19.7% of the controls had mild or greater deficits ($p = 0.007$).

Long-term follow-up

Exposure to high-intensity therapy combined with prolonged immune suppression after HCT increases the risk of adverse sequelae, and hence the healthcare needs, among survivors. Healthcare utilization by long-term HCT survivors [104] revealed that 98% of allogeneic HCT recipients and 94% of autologous HCT recipients reported medical contact a decade after HCT. Whereas cancer-related visits decreased with time from HCT, the prevalence of general physical examinations increased. This study demonstrates that primary physicians assume increasing responsibility for providing healthcare for long-term HCT survivors, thus making it critical that there be standardized guidelines for follow-up of these survivors. The overall goal of standardized guidelines is early identification of treatment-related complications, potentially allowing for early intervention with resultant reductions in morbidity and mortality and attendant reductions in healthcare costs.

To accomplish early detection and prevention of life-threatening complications, HCT survivors should undergo annual comprehensive physical examination that includes screening for functional and psychosocial consequences of treatment and education regarding key aspects of health promotion. The Center for International Blood and Marrow Transplantat Research (CIBMTR), European Group for Blood and Marrow Transplantation (EBMT), and American Society for Bone Marrow Transplantation (ASBMT) have developed recommendations for screening and prevention practices for HCT survivors [105]. These recommendations were recently updated [106], and concentrate on risks faced by patients beyond 6 months following transplantation. Most of these recommendations are derived from studies that identified specific complications in long-term survivors and the risk factors associated with them. The recommendations are organized by tissue/organ system, with details regarding potential late effects, the known risk factors, and recommendations for monitoring tests and preventive measures. The recommendations are also organized by time after HCT, detailing suggested recommendations at 6 months, 1 year, and then annually.

Comprehensive guidelines for follow-up of pediatric cancer survivors (including patients who have been treated with HCT) have been developed by the Children's Oncology Group (COG) (www.survivorshipguidelines.org). The COG guidelines are evidence based (utilizing established associations between therapeutic exposures and late effects to identify high-risk categories) and consensus based (matching the magnitude of risk of complications with intensity of screening). Since treatment exposures vary by primary diagnosis, HCT type, patient age, and treatment era, *a therapy-based approach* was chosen. These guidelines have been developed as a resource for clinicians who provide ongoing healthcare to HCT survivors. The COG Guidelines are intended for use beginning 2 years or longer after completion of therapy (or date of HCT), and provide a framework for monitoring of late effects in survivors. The recommendations for periodic screening evaluations provided in these guidelines are appropriate for asymptomatic survivors who present for routine medical follow-up. Table 103.2 gives an overview of the key content areas in the guidelines. The major difference between the COG guidelines and those developed by EBMT/CIBMTR/ASBMT is the fact that unlike the latter, the former utilize the cumulative therapeutic exposures to generate a tailored list of potential late effects and the recommended screening for early detection of those late effects. The intensity of screening is determined by whether the patient is at standard risk or increased risk due to cumulative therapeutic exposures and/or host/demographic characteristics. This provides a greater level of granularity and specificity to the screening that the patient undergoes, and therefore eliminates the possibility of over- or under-screening.

Table 103.2 Key content areas in guidelines for long-term follow-up of survivors

Therapeutic agent	All major therapeutic agents used in the treatment, including pre-HCT chemotherapy, radiation, surgery, and transfusions, and HCT-related preparative regimens
Potential late effects	Sequelae observed after treatment; potentially resulting from pre-HCT therapy, preparative regimens used for HCT, or as a result of post-HCT events (psychosocial, dermatologic, ocular, audiologic, oral, craniofacial, cardiovascular, pulmonary, hepatic, gastrointestinal, renal, musculoskeletal, neurologic, endocrine, reproductive consequences, immune reconstitution and risk of infection, and second malignant neoplasms)
Potential risk factors	Host factors (gender, age at therapeutic exposure, genetic predisposition, ethnicity); medical conditions (premorbid/comorbid conditions); therapeutic exposures (cumulative dose); health behaviors (diet, smoking, exercise)
Highest risk categories	Host factors; treatment factors; medical conditions; genetic predisposition
Periodic evaluations	Health history; clinical examinations; laboratory analysis; diagnostic imaging; psychosocial assessments
Minimum recommended frequency	Baseline and periodic testing and recommendations based on risk factors and magnitude of risk (supported by literature and clinical experience)
Health protective counseling	To prevent/reduce risk of complications and promote early detection
General healthcare	Linked to recommendations per US Preventive Services Task Force
Cancer screening guidelines	Based on ACS recommendations for standard risk. For increased risk of SMNs (therapeutic exposures, family history, or premorbid/comorbid conditions) modified guidelines tailored to the magnitude of risk will be available

The high burden of morbidity suffered by HCT survivors necessitates that strategies be developed for prevention or early detection of these complications. However, many survivors are no longer under the care of transplant centers, and community healthcare providers may be unfamiliar with the unique needs of the HCT survivors. Despite the differences in approach used by the two sets of guidelines described above, having a set of consensus-based guidelines represents a huge first step in standardizing the long-term follow-up of HCT survivors. The next important step is to ensure that these guidelines are disseminated and accepted by the healthcare providers and also by agencies that reimburse the costs of the screening tests. Adherence to these guidelines, the yield from such recommendations, and the cost-effectiveness of standardized follow-up of the HCT survivors will provide evidence for the refinement of these guidelines.

CHAPTER 104

Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation

Smita Bhatia and Ravi Bhatia
University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

The number of patients undergoing hematopoietic cell transplantation (HCT) for malignant or non-malignant disorders has increased steadily over the past four decades. Improvement in survival after HCT and extended follow-up of the growing population of HCT survivors have resulted in an increasing focus on issues related to long-term complications (see Chapter 103). An important and potentially devastating complication of HCT is the occurrence of subsequent malignant neoplasms (SMNs) [1–3]. The magnitude of risk of SMNs after HCT has ranged from 4- to 11-fold that of the general population. The estimated actuarial incidence is reported to be 3.5% at 10 years, increasing to 12.8% at 15 years among recipients of allogeneic HCT (Table 104.1) [4].

Risk factors associated with the development of SMNs include: exposure to chemotherapy and radiation prior to HCT; use of total body irradiation (TBI) and high-dose chemotherapy for myeloablation; human leukocyte antigen (HLA) non-identity; immunodeficiency after HCT aggravated by the use of immunosuppressive drugs for prophylaxis and treatment of graft-versus-host disease (GVHD) such as monoclonal and polyclonal antibodies and T-cell depletion; and infection with viruses such as Epstein–Barr virus (EBV) and hepatitis B and C viruses. However, assessment of risk factors for all SMNs in aggregate is somewhat artificial because of the heterogeneous nature of these malignancies, with differing clinicopathologic features, distinct pathogenesis, and hence very distinct risk factors associated with their development. It has therefore become conventional practice to classify SMNs after HCT into three distinct groups:

1. therapy-related myelodysplastic syndrome (t-MDS) and acute myeloid leukemia (AML) (t-MDS/t-AML);
2. lymphoma (including lymphoproliferative disorders);
3. solid tumors.

Leukemia and lymphoma develop relatively early in the post-transplantation period. On the other hand, solid tumors have a longer latency period and are being increasingly described because of improved survival after HCT and longer follow-up (Figure 104.1). In this chapter, we discuss the three types of SMNs seen among patients undergoing HCT. The emphasis is on clinical presentation of these malignancies, the magnitude of risk and risk factors associated with their development, insights into their pathogeneses, and the treatment options and outcome of patients with these malignancies. The chapter concludes with a brief summary regarding surveillance recommendations for early detection of SMNs.

MDS and AML after autologous HCT

Autologous HCT is now the treatment of choice for patients with Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) who have a suboptimal response to initial therapy, those with refractory or relapsed disease, and those at high risk for relapse after conventional therapy. Autologous HCT is also being increasingly used in specific clinical situations among patients with multiple myeloma.

With improvement in survival following autologous HCT, t-MDS and t-AML are emerging as the major cause of non-relapse mortality [2,5–7]. The cumulative probability of t-MDS/t-AML reported in the literature has ranged from 1.1% at 20 months [8] to 24.3% at 43 months [9] after autologous HCT, depending on the size of the population studied and the completeness of follow-up. The median time to development of t-MDS/t-AML is 12–24 months (range 4 months to 6 years) after HCT. The magnitude of risk of t-MDS/t-AML is higher and the time to development of t-MDS/t-AML is shorter after HCT compared with conventional chemotherapy and radiation. However, the difference in the magnitude of risk may arise, in part, because there are fewer long-term survivors of conventional therapy who have been exposed to multiple salvage therapies.

Clinicopathologic syndromes

Two types of t-MDS/t-AML are recognized in the World Health Organization classification depending on the causative therapeutic exposure: an alkylating agent/radiation-related type and a topoisomerase II inhibitor-related type [10]. Recent reports suggest that patients with multiple myeloma exposed to lenalidomide may be at increased risk for t-MDS/t-AML. However, many cases fail to fall into distinct categories because often patients are exposed to multiple classes of drugs.

Alkylating agent/radiation-related t-MDS/t-AML

Alkylating agent-related t-MDS/t-AML usually appears 4–7 years after exposure to the mutagenic agent. Approximately two-thirds of patients present with MDS and the remainder with AML with myelodysplastic features [11,12]. Patients frequently present with cytopenias, often pancytopenia. Multilineage dysplasia is often present. There is a high frequency of the multidrug-resistance

Table 104.1 Magnitude of risk and populations at increased risk of subsequent malignant neoplasms after hematopoietic cell transplantation

Study	Study design	Sample size/number of SMNs	Primary diagnoses; type of HCT	Magnitude of risk and risk factors
Witherspoon et al. [92]	Retrospective cohort study	2246/35 leukemia, lymphoma, solid malignancies	Autologous or allogeneic HCT	6.7-fold increased risk compared with general population Acute GVHD treated with ATG or antiCD3 antibody, TBI was associated with increased risk of SMNs
Bhatia et al. [2]	Retrospectic cohort study	2150/53 leukemia, lymphoma, solid malignancies	All hematologic malignancies, inborn diseases of immune system Autologous and allogeneic HCT	11.6-fold increased risk compared with general population Cumulative probability: 9.9% at 13 years for all SMNs; 1.6% at 4 years for PTLD; 5.6% at 13 years for solid malignancies. T-cell depletion, use of ATG, unrelated donor HCT, primary immune deficiency associated with increased risk of PTLD
Deeg et al. [129]	Retrospective cohort	700/23 leukemias (ALL), solid tumors and lymphomas	Severe aplastic anemia Allogeneic HCT	Cumulative probability: 14% at 20 years Azathioprine; diagnosis of Fanconi anemia; irradiation and age at HCT in the non-Fanconi cohort
Kolb et al. [130]	Retrospective cohort study	1036/53 leukemia, lymphoma, solid malignancies	Leukemia, lymphoma, inborn diseases of hematopoietic and immune systems, severe aplastic anemia Autologous and allogeneic	Cumulative probability: 3.5% at 10 years 3.8-fold increased risk compared with general population Older age at HCT and treatment of chronic GVHD with cyclosporine associated with increased risk
Baker et al. [131]	Retrospective cohort study	3372/147 leukemia, lymphoma and solid malignancies	All malignancies and metabolic disorders; immune deficiency; aplastic anemia Autologous and allogeneic	8.1-fold increased risk compared with general population Cumulative incidence: 6.9% at 20 years for any malignancy; 1.4% at 10 years for PTLD; 1.4% at 10 years for MDS/AML; 3.8% at 20 years for solid tumors

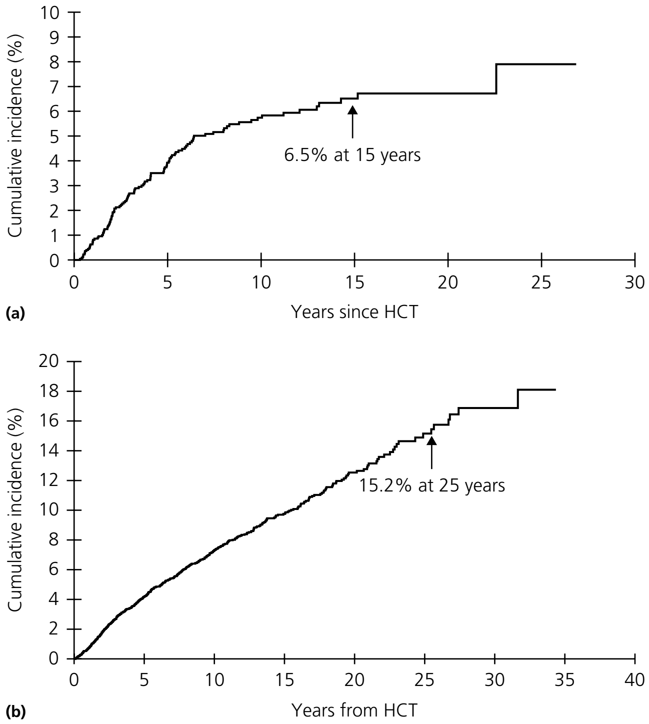

Figure 104.1 (a) Cumulative probability of therapy-related myelodysplasia and acute myeloid leukemia in a cohort of patients undergoing autologous hematopoietic cell transplantation (HCT) for Hodgkin lymphoma or non-Hodgkin lymphoma – a single institution experience. (b) Cumulative probability of solid malignancies after HCT in patients undergoing autologous or allogeneic HCT at a single institution.

phenotype. In addition, there is a high incidence of abnormalities involving chromosomes 5 [–5/del(5q)] and 7 [–7/del(7q)].

Topoisomerase II inhibitor-related AML

Studies in which primary human CD34$^+$ cells were exposed to etoposide in vitro provide evidence that etoposide can directly induce *MLL* rearrangements in hematopoietic cells. Stable genome rearrangements originating within the *MLL* translocation breakpoint hotspot were readily detected in etoposide-treated cells. The spectrum of illegitimate repair included frequent *MLL* partial tandem duplications and translocations, and minor populations containing deletions or insertions. Several clones had breakpoints that localize to *MLL* bcr sequences identified at rearrangement junctions in therapy-related leukemias [13].

AML secondary to topoisomerase II inhibitors often does not have a preceding myelodysplastic phase, and presents as overt acute leukemia, often with a prominent monocytic component [14,15]. The latency period between the initiation of treatment with topoisomerase II inhibitors and the onset of leukemia is brief, ranging from 6 months to 5 years, with a median of 2–3 years [15]. Most often, this type of t-AML is associated with balanced translocations involving chromosome bands 11q23 or 21q22 [15]. Other translocations including inv(18)(p13q22) or t(17,19)(q22;q12) have been reported [14,16].

Lenalidomide-related t-MDS/t-AML

There is emerging evidence that lenalidomide may be associated with an increased occurrence of t-MDS/t-AML. Two of three recent phase III, placebo-controlled, randomized trials reported a higher incidence of t-MDS/t-AML; however, the number of events was small [17–19]. An analysis of pooled data from 11 industry-sponsored trials suggested that there was no correlation between the development of t-MDS/t-AML and the cumulative dose or duration of lenalidomide received [20]. These observations suggest that large numbers of patients exposed to lenalidomide with comprehensive and complete follow-up are needed before the risk of t-MDS/t-AML can be described in this population with precision.

Clinical diagnosis

Cytopenias and dysplastic changes on marrow examination can often be seen in isolation in many patients after autologous HCT, many of whom may not subsequently develop t-MDS/t-AML. Therefore, the Dana-Farber Cancer Institute group has proposed [21] that the diagnosis of t-MDS/t-AML after HCT be based on the presence of:

1. significant marrow dysplasia in at least two cell lines;
2. peripheral cytopenias without alternative explanations;
3. blast counts in marrow defined by the French–American–British classification, or the presence of clonal cytogenetic abnormality.

Risk factors for t-MDS/t-AML after HCT

Factors associated with an increased risk of t-MDS/t-AML include host factors (older age at HCT) [2,22], pre-transplantation therapy with alkylating agents, topoisomerase II inhibitors, and radiation therapy [6,9], method of hematopoietic cell mobilization (etoposide) [2,6], and transplantation conditioning with TBI [23,24] (Table 104.2). Some other factors include a lower number of $CD34^+$ cells infused at HCT [25] and a history of multiple transplantations [24]. Therefore, t-MDS/t-AML appears to be related to perhaps the cumulative effect of pre-transplantation chemotherapy and radiotherapy, transplantation-related factors such as the hematopoietic cell priming, and transplantation conditioning regimens.

The significant impact of primary chemotherapy and radiotherapy on the risk of t-MDS/t-AML after HCT points to an origin of events prior to HCT [6,9]. Moreover, the nature of the pre-transplantation cytotoxic exposure (alkylating agent versus topoisomerase II inhibitor) has a significant impact on the type of t-MDS/t-AML that evolves in the post-transplantation period, reinforcing this observation. A role for pre-transplantation exposures is further supported by the observation that specific cytogenetic abnormalities observed post-transplantation have also been observed in the pre-transplantation marrow or peripheral blood graft among patients who develop t-MDS/t-AML after HCT [26,27]. Abruzzese et al. [27] reported that nine of 12 cases of t-MDS/t-AML studied demonstrated abnormal cells in pre-transplantation bone marrow samples using fluorescence in situ hybridization (FISH). Lillington et al. [26]. reported that significant levels of clonally abnormal cells could be detected in samples obtained prior to high-dose therapy in 20 of 20 patients with t-MDS/t-AML using single-locus specific FISH probes to detect loss of chromosomal material from 5q31, 7q22, and 13q14. In comparison, only three of 24 patients who had not developed t-MDS/t-AML had abnormal clones in pretreatment samples. These studies support a role for genetic abnormalities induced by prior cytotoxic chemotherapy in the etiology of t-MDS/t-AML. However, prospective studies of larger groups of patients are warranted to determine the significance of these observations.

An association of TBI with increased risk for t-MDS/t-AML [23,24]. raises the possibility that the disease may arise from residual hematopoietic cells that persist in the patient despite treatment with high-dose chemotherapy, rather than from reinfused hematopoietic cells, although it is also possible that TBI-induced alteration in the hematopoietic microenvironment may contribute to the development of t-MDS/t-AML. Therefore, it is unclear whether t-MDS/t-AML arises from the graft, from residual cells in the patient, or as a result of a damaged microenvironment.

Table 104.2 Magnitude of risk and populations at increased risk of therapy-related leukemia after hematopoietic cell transplantation

Study	Study design	Sample size/ number of SMNs	Primary diagnoses; type of HCT	Magnitude of risk and risk factors
Krishnan et al. [6]	Retrospective cohort study Nested case–control study	612/22 MDS/AML	Hodgkin lymphoma Non-Hodgkin lymphoma Autologous HCT	Cumulative probability of MDS/AML: 8.6% at 6 years Stem-cell priming with VP-16, pre-HCT radiation associated with increased risk of t-MDS/t-AML
Milligan et al. [24]	Retrospective cohort design	4998/66 MDS/AML	Hodgkin lymphoma Non-Hodgkin lymphoma Autologous HCT	5-year cumulative probability: 4.6% for HL and 3% for NHL. Older age at HCT, diagnosis of HL, exposure to TBI, multiple HCT, years between diagnosis were associated with increased risk of MDS/AML

A higher risk of t-MDS/t-AML has been demonstrated among recipients of CD34-enriched cells isolated from peripheral blood after chemotherapy priming and growth factors, as compared with autologous transplantation using $CD34^+$ cells from the bone marrow without pretreatment [2,6]. Potential explanations offered for this observation include harvesting of hematopoietic precursor cells damaged by chemotherapy at a time before they have completed DNA repair or an overrepresentation of damaged cells in the mobilized product [28]. Supporting this hypothesis is a study by Krishnan et al. [6] demonstrating an increased risk of t-AML with 11q23 abnormalities among patients with HL and NHL mobilized with high doses of etoposide for collection of hematopoietic cells prior to autologous HCT.

Friedberg et al. [25] reported an increased risk of t-MDS/t-AML among patients who received a significantly smaller number of cells re-infused per kilogram of body weight. In the setting of low hematopoietic cell numbers, reconstitution of bone marrow clearly may result in a greater proliferative stress, which may increase susceptibility to irreversible DNA damage associated with t-MDS. These findings are consistent with in vitro data suggesting an increased proliferative stress placed upon committed progenitors at the expense of the primitive progenitors, as shown later in the chapter [29]. Alternatively, reduced ability to harvest cells could indicate an existing defect in marrow function. Kalaycio et al. demonstrated that patients who had difficulty harvesting adequate numbers of hematopoietic cells were at an increased risk of developing t-MDS/t-AML independent of the risk conferred by increased exposure to prior cytotoxic therapies [30].

Pathogenesis of t-MDS/t-AML

t-MDS and t-AML are clonal hematologic disorders that are the consequence of an acquired somatic mutation induced by cytotoxic therapy in hematopoietic stem and progenitor cells which confers a proliferative and/or survival advantage. Improved understanding of the molecular pathogenesis of t-MDS/t-AML may allow the development of strategies to identify populations at risk and modify therapies in order to decrease the morbidity and mortality associated with this complication. Furthermore, t-MDS/t-AML offers a unique perspective on mutagen-induced carcinogenesis and the role of genetic susceptibility to cancer in humans.

t-MDS/t-AML after autologous HCT appears to result from genetic damage to the stem and/or progenitor cell from pretransplant cytotoxic treatment, which may be potentiated by the transplant process itself through several mechanisms, including hematopoietic cell mobilization, collection, and storage, chemotherapy and radiation used for high-dose therapy, and the stress of engraftment and hematopoietic regeneration on the hematopoietic precursors [28].

Genetic lesions associated with t-MDS/t-AML

Loss of chromosome 5 or del(5q) and loss of chromosome 7 and del(7q) are recurring abnormalities in t-MDS/t-AML. These abnormalities are also seen in AML evolving from MDS and de novo AML in elderly subjects. This has led to a search for candidate tumor suppressor genes in these regions. Several groups have attempted to identify commonly deleted segments and to derive transcript maps of these segments [31,32]. The majority of patients with 5q deletions exhibit losses at the 5q31 locus, with deletions in 5q33 being seen in some patients. Chromosomal segment 7q22 is a common site of chromosome 7 deletions. This observation has led to a search for candidate tumor suppressor genes in these chromosomal regions. Identification of a commonly deleted tumor suppressor gene has been elusive thus far. It is possible that haploinsufficiency and reduced gene dosage for critical genes involved in hematopoiesis may sufficiently alter the balance between growth and differentiation to induce dysplastic hematopoiesis [33]. The role of specific genes has been evaluated. For example, the *APC* gene located in the commonly deleted 5q region has been studied. Mice with the *Apcmin* allele that results in a loss of APC function showed no abnormality in steady-state hematopoiesis but had reduced long-term stem-cell function and developed an MDS/myeloproliferative phenotype over time [34], supporting a potential role for *Apc* haploinsufficiency in the MDS phenotype in patients with del (5q).

Molecular analysis of a 2.5-Mb commonly deleted segment of chromosome band 7q22 has failed to uncover a candidate tumor suppressor gene. Abnormalities in chromosome 7 are associated with myeloid leukemias in genetically predisposed individuals, such as Fanconi anemia or neurofibromatosis type 1 [35,36], raising the possibility that similar predisposition may be present in patients with t-MDS/t-AML with loss of chromosome 7. Further, 5q and 7q deletions in familial platelet disorder with leukemia are associated with mutations or deletions of a single *AML1* allele [37]. Balanced translocations involving the *AML1* gene have also been associated with t-MDS/t-AML in patients exposed to topoisomerase II inhibitors [38,39]. Transgenic expression of AML1-ETO leads to immortalization of murine myeloid progenitors but not overt leukemia; additional mutations are required for leukemogenesis [40]. Therefore, altered AML1 function may have a major role in dysregulation of hematopoietic growth and genomic instability and predispose to leukemia through a multistep process.

The *MLL* gene located at chromosome band 11q23 is frequently involved in translocations associated with topoisomerase II inhibitors. *MLL* has a major role in developmental regulation [41]. Altered MLL function, as with AML1, may dysregulate hematopoietic growth and genomic instability, and predispose to leukemia through a multistep process. The long latency period to onset of leukemia in the knock-in mouse suggests that additional genetic changes are required for evolution of t-AML [42].

Genetic susceptibility: polymorphisms in drug-metabolizing enzymes

The interindividual variability in risk of t-MDS/t-AML is likely related to common polymorphisms in low-penetrance genes that regulate the availability of active drug metabolite, or those responsible for DNA repair.

Drug metabolism: Allan et al. utilized a candidate gene approach to examine associations between polymorphisms in the glutathione *S*-transferase genes (*GSTM1, GSTT1*, and *GSTP1*) and t-MDS/t-AML [43]. Relative to de novo AML, the *GSTP1* codon 105 allele occurred more often among t-MDS/t-AML patients with prior exposure to chemotherapy [odds ratio (OR) 2.7, 95% confidence interval (CI) 1.4–5.1], particularly among those with prior exposure to known GSTP1 substrates (OR 4.3, 95% CI 1.4–13.2) and not among t-MDS/t-AML patients with exposure to radiation alone.

Drug transport: P-glycoprotein (encoded by MDR1) traps hydrophobic drugs in the plasma membrane of cells and effluxes them using an ATP-dependent process; many chemotherapeutic drugs are substrates of this protein. A number of polymorphisms exist in the *MDR1* gene, some proposed to be functional and those with loss of function have been evaluated as risk factors for t-MDS/t-AML [44].

DNA repair: Individuals with altered DNA repair mechanisms are likely susceptible to the development of genetic instability that drives the process of carcinogenesis as it relates to t-MDS/t-AML.

Mismatch repair (MMR) functions to correct mismatched DNA base pairs that arise as a result of misincorporation errors that have avoided polymerase proofreading during DNA replication [45]. Defects in the MMR pathway result in genetic instability or a mutator phenotype, manifested by an elevated rate of spontaneous mutations characterized as multiple replication errors in simple repetitive DNA sequences (microsatellites) – functionally identified as microsatellite instability (MSI). Approximately 50% of t-MDS/t-AML patients have MSI, associated with methylation of the MMR family member MLH1 [46,47], low expression of MSH2 [48], or polymorphisms in MSH2 [49].

Double-strand breaks (DSBs) in DNA may lead to loss of genetic material, resulting in chromosomal aberrations. High levels of DSBs arise following radiation and chemotherapy exposures. Cellular pathways available to repair DSBs include homologous recombination (HR), non-homologous end-joining (NHEJ), and single-strand annealing (SSA). RAD51 is one of the central proteins in the HR pathway, functioning to bind to DNA and promote ATP-dependent homologous pairing and strand transfer reactions. *RAD51-G-135C* polymorphism is significantly over-represented in patients with t-MDS/t-AML compared with controls (C allele: OR 2.7) [50]. XRCC3 also functions in the HR DSB repair pathway by directly interacting with and stabilizing RAD51 [51,52]. XRCC3 is a paralog of RAD51, also essential for genetic stability [53,54]. A polymorphism at codon 241 in the *XRCC3* gene results in a Thr → Met amino acid substitution [55]. The variant *XRCC3–241Met* allele has been associated with a higher level of DNA adducts compared with cells with the wild-type allele, implying aberrant repair [56], and has also been associated with increased levels of chromosome deletions in lymphocytes after exposure to radiation [57]. Although *XRCC3-Thr241Met* was not associated with t-MDS/t-AML (OR 1.4, 95% CI 0.7–2.9), a synergistic effect resulting in an eightfold increased risk of t-MDS/t-AML (OR 8.1, 95% CI 2.2–29.7) was observed in the presence of *XRCC3–241Met and RAD51–135C* allele in patients with t-MDS/t-AML compared with controls [50]. The NHEJ pathway joins broken DNA ends containing very little homology. This process is not always precise and can result in small regions of non-template nucleotides around the site of the DNA break, potentially relevant in MLL translocation associated with t-MDS/t-AML [58].

The *base excision repair (BER)* pathway corrects individually damaged bases occurring as a result of ionizing radiation and exogenous xenobiotic exposure. The XRCC1 protein plays a central role in the BER pathway and also in the repair of single-strand breaks, by acting as a scaffold and recruiting other DNA repair proteins [59,60]. The protein also has a BRCA1 C-terminus (BRCT) domain – a characteristic of proteins involved in DNA damage recognition and response. The presence of variant *XRCC1–399Gln* has been shown to be protective for t-MDS/t-AML [61].

Nucleotide excision repair (NER) removes structurally unrelated bulky damage induced by radiation and chemotherapy. The NER pathway is linked to transcription, and components of the pathway comprise the basal transcription factor IIH complex (TFIIH), which is required for transcription initiation by RNA polymerase II. One of the genes involved in the NER pathway (*ERCC2*) is a member of the TFIIH complex. The polymorphic Gln variant (*ERCC2 Lys751Gln*) is associated with t-MDS/t-AML [62].

Neither polymorphism demonstrated a significant association. However, an interactive effect was detected such that *MDM2* TT

TP53 Arg/Arg double homozygotes, and individuals carrying both an *MDM2* G allele and a *TP53* Pro allele, were at increased risk of chemotherapy-related t-MDS/t-AML. Knight et al. conducted a genome-wide association study (GWAS) in patients who had developed t-MDS/t-AML and healthy controls [63]. They identified three SNPs [rs1394384 (OR 0.3, 95% CI 0.2–0.6), rs1381392 (OR 2.1, 95% CI 1.3–3.4), and rs1199098 (OR 0.5, 95% CI 0.3–0.8)] to be associated with t-MDS/t-AML with chromosome 5/7 abnormalities. rs1394384 is intronic to *ACCN1*, a gene encoding an amiloride-sensitive cation channel that is a member of the degenerin/epithelial sodium channel; rs1199098 is in linkage disequilibrium with *IPMK,* which encodes a multikinase that positively regulates the prosurvival AKT kinase and may modulate Wnt/beta-catenin signaling; rs1381392 is not near any known genes, miRNAs, or regulatory elements, although it lies in a region recurrently deleted in lung cancer. The investigators were able to confirm findings in an independent replication cohort.

The *p53* gene has a critical role in DNA damage response signaling, affecting cell cycle, cell death, and DNA repair pathways. Abnormal *p53* activity could lead to a reduced ability to repair DNA damage, resulting in genomic instability and increased susceptibility to leukemogenesis. In patients with de novo MDS and AML, *p53* mutations are seen in fewer than 10% of patients. Ben-Yehuda et al. [64] identified *p53* mutations in 38% of 21 t-MDS/t-AML patients. Mutations were non-germline and restricted to leukemic cells. Horiike et al. [49] identified *p53* mutations in six of 12 patients with t-MDS and chromosome 5 and/or 7 losses, but did not observe any *p53* mutations in nine other patients without chromosome 5 and/or 7 involvement. Christiansen et al. [65] observed mutations in *p53* in 21 of 77 patients (27%) with t-MDS/t-AML; 19 of these 21 patients with mutations had received alkylating agents. *p53* mutations were associated with deletion or loss of 5q and a complex karyotype, were more common in elderly patients, and were associated with an extremely poor prognosis [65]. These studies indicate that *p53* mutations may be observed in certain cytogenetic and prognostic subsets of patients with t-MDS/t-AML, but do not identify a clear role for *p53* mutations in the pathogenesis of this disorder.

Mouse strains resistant or susceptible to t-AML induced by the alkylator ethyl-*N*-nitrosourea (ENU) were analyzed to identify genes that regulate t-AML susceptibility. Thirteen quantitative trait loci (QTL) were significantly associated with ENU-induced leukemogenesis. These QTL contained several genes that could contribute to leukemogenesis, including p53, DNA repair, and apoptosis-regulating genes. These results suggest that susceptibility to alkylator-induced leukemia may be a complex trait related to multiple genes [66].

Genetic instability

Genetic instability is hypothesized to be an early event in the development of malignancy, allowing the accumulation of multiple mutations in the same cell over time, and evolution of a clonal malignant population. Telomeres are non-coding regions of DNA that provide a cap at the ends of chromosomes and prevent dicentric fusion and other chromosomal aberrations [67]. Each somatic cell division is associated with a loss of telomere length. Cumulative telomere shortening can impose a limit on cell divisions and lead to cell senescence. Telomere shortening is also associated with genetic instability [68]. In hematopoietic tissues, there is progressive shortening of telomere length through life, with considerable variability between age-matched individuals. Following HCT, the increased replicative demand on hematopoietic cells associated with hematopoietic regeneration can lead to accelerated telomere shortening. The extent of telomere shortening correlates with the number of cells transplanted. In autologous HCT recipients, telomere length in the transplanted cells is already short because of prior chemotherapy, older age at HCT, increased replicative stress on the hematopoietic cells because of a small number of cells transplanted, or other unknown causes. Patients who developed t-MDS/t-AML after autologous HCT showed accelerated telomere shortening compared with matched controls who did not develop t-MDS/t-AML [69]. Telomere alterations preceded the onset of t-MDS and were independent of other known risk factors for t-MDS/t-AML on multivariate analysis. Constitutional hypomorphic telomerase mutations are seen with increased frequency in patients with AML, suggesting that inherited mutations in telomerase reverse transcriptase (TERT) that reduce telomerase activity may be risk factors for AML.

Hematopoietic abnormalities

Autologous HCT for HL and NHL has been reported to be associated with hematopoietic abnormalities including marked and possibly permanent reduction in primitive progenitor long-term culture-initiating cells and committed progenitor colony-forming cell numbers, altered progenitor expansion potential, and microenvironmental defects [29,70–72]. These abnormalities may be related in part to damage to hematopoietic cells from pre-transplant chemotherapy because hematopoietic defects can also be seen in pre-transplant samples [29,71,72]. A longitudinal study of patients undergoing autologous HCT for lymphoma revealed a significant reduction in primitive and committed progenitors in patients prior to HCT compared with healthy controls. Further profound and persistent reduction in primitive progenitors, but only transient reduction in committed progenitors, was seen after HCT, consistent with extensive proliferation and differentiation of the committed progenitors and subsequent depletion of primitive progenitors during hematopoietic regeneration post-HCT. Patients within this cohort who developed t-MDS/t-AML had reduced recovery of committed progenitors and poorer telomere recovery post-HCT, possibly indicating a functional defect in primitive hematopoietic cells [29]. In a large population-based study, the use of growth factor was independently associated with a 1.5-fold increased risk of developing t-MDS/t-AML. Extensive proliferation of hematopoietic cells bearing genotoxic damage post-transplant may have a role in the establishment and amplification of an abnormal clone. Alternatively, the numerous replication cycles imposed on hematopoietic stem cells after HCT may result in excessive shortening of telomeres in descendent cells (as discussed above). Telomeric shortening may be associated with genomic instability and chromosomal abnormalities, and could contribute to the pathogenesis of t-MDS/t-AML [68].

$CD34^+$ cells in the graft from lymphoma patients also show reduced migration compared with normal $CD34^+$ cells. The in vitro migratory capacity of $CD34^+$ cells in the graft correlated with the speed of hematopoietic recovery after transplantation [73]. Therefore, pre-transplant chemotherapy may also lead to a reduced engraftment potential of primitive progenitor cells. This observation is consistent with experimental data showing that exposure to chemotherapeutic agents results in long-lasting damage to the repopulating ability of hematopoietic stem cells as measured in competitive repopulating unit assays in mice [74]. HCT may also be associated with defects in the marrow hematopoietic microenvironment, including reduction in stromal precursor growth and reduced capacity to support the growth of myeloid progenitors and B cell progenitors [71,75,76]. Microenvironmental defects may contribute to hematopoietic abnormalities after transplantation. Recent studies support the importance of the hematopoietic microenvironment in MDS pathogenesis. Repeated sub-lethal irradiation of mice resulted in bone marrow (BM) dysfunction with features of MDS including low white blood cell (WBC) counts, macrocytic anemia, and reduced platelets and megakryocytes. BM dysfunction was associated with increased BM angiogenesis, vascular endothelial growth factor (VEGF), and activation of the transcription factor nuclear factor-kappa B (NFκB). Tumor necrosis factor (TNF)-α-deleted mice were protected from irradiation effects [77]., suggesting that radiation-mediated TNF-α induction may contribute to BM dysfunction and t-MDS. Interestingly, de novo MDS patients also express high levels of TNF-α [78]. Deletion of the microRNA processing factor Dicer1 in mouse osteoblast progenitors resulted in hematopoietic abnormalities leading to the development of MDS and AML, associated with reduced expression of the *Sbds* gene that is mutated in Schwachman–Bodian–Diamond syndrome, an inherited human marrow failure disorder [79]. Deletion of *Sbds* in osteoblast progenitors also induced marrow dysfunction and myelodysplasia. These results support a role for perturbation of microenvironmental cells in hematopoietic defects in MDS.

Gene expression profiling

Yeoh et al. [80] reported that the gene expression profile of ALL cells at diagnosis was predictive of therapeutic outcomes, including the risk of development of t-MDS/t-AML. Qian et al. [81]. performed gene expression profiling of CD34$^+$ hematopoietic progenitor cells from t-AML patients. This analysis identified different subtypes of t-AML with characteristic gene expression patterns. Common to each subgroup were gene expression patterns characteristic of arrested differentiation in early progenitor cells. Extension of such studies may enhance our understanding of the molecular pathways involved in t-AML. Li et al. performed microarray analysis of gene expression in patients who developed t-MDS after autologous HCT for HL or NHL (cases) and patients who did not develop t-MDS after autologous HCT (aHCT) (controls) [82]. To evaluate gene expression changes pre-HCT, peripheral blood stem cell (PBSC) samples obtained from t-MDS cases and controls before aHCT were studied. Patients who later developed t-MDS showed significantly altered gene expression compared with control subjects, related to mitochondrial function, ribosomes, DNA repair, and hematopoietic stem-cell regulation. Additional alterations in cell-cycle regulatory genes were seen on progression to overt t-MDS/t-AML. PBSC CD34$^+$ cells from patients who developed t-MDS demonstrated altered mitochondrial function, increased reactive oxygen species (ROS), reduced ROS detoxification, and enhanced DNA damage after therapeutic exposure. These results indicate that genetic programs associated with t-MDS/t-AML are perturbed long before disease onset, and are consistent with previous studies indicating a potential role for abnormalities in stem-cell growth, DNA repair, and checkpoint response in t-MDS/t-AML pathogenesis.

Outcome of patients with t-MDS/t-AML after autologous HCT

The response to chemotherapy is inferior for t-MDS/t-AML compared with de novo leukemia; The average complete remission rate ranges between 35 and 40%, and overall long-term survival is poor (reviewed in [83]). As a result, allogeneic transplantation has been evaluated as a therapeutic modality for t-MDS/t-AML. There are few data about outcome after allogeneic HCT for t-MDS/t-AML arising after aHCT, since all prevous reports have combined combined t-MDS/t-AML arising after conventional therapy with that arising after aHCT [84–87]. All these studies emphasize the important role of cytogenetics in determining outcome.

Yakoub-Agha et al. identified predictive factors of outcome for 70 patients with t-MDS/t-AML undergoing allogeneic HCT between 1980 and 1998 [85]. With a median follow-up of 7.9 years after HCT, the estimated 2-year overall survival and event-free survival rates were 30 and 28%, respectively. Age greater than 37 years, male gender, positive recipient cytomegalovirus serology, absence of complete remission at HCT, and intensive schedules used for conditioning were associated with poor outcome.

Armand et al. examined the contribution of cytogenetics to survival, relapse, and non-relapse mortality for 80 patients with t-MDS/t-AML [84]. Cytogenetics was the strongest prognostic factor for outcome. The three categories included the following: (i) favorable [t(8;21), inv(16) or t(16;16), t(15;17)]; (ii) intermediate [normal, +8, del(9q), 11q23, t(9;22), t(6;9), other]; and (iii) unfavorable [−5, del(5q), or −7, abnormal 3q, complex, not obtained/not available]. After accounting for cytogenetics, patients with t-MDS/t-AML had an equivalent outcome to those with de novo disease.

Kroger et al. described the outcome in 461 patients with t-MDS/t-AML treated with allogeneic HCT between 1981 and 2006 [86]. The cumulative incidence of non-relapse mortality and relapse at 3 years was 37 and 31%, respectively. Relapse was significantly higher in patients not in complete remission at the time of HCT ($p = 0.002$), abnormal cytogenetics ($p = 0.005$), older age ($p = 0.03$), and t-MDS ($p = 0.04$). Using age (<40 years), abnormal cytogenetics, and not being in complete remission at the time of transplantation as risk factors, three different risk groups with overall survival rates of 62, 33, and 24%, respectively, could be easily distinguished.

Litzow et al. analyzed outcomes in 868 persons with t-AML ($n = 545$) or t-MDS ($n = 323$) receiving allogeneic transplants from 1990 to 2004 [87]. A myeloablative regimen was used for conditioning in 77%. Disease-free survival (DFS) and overall survival (OS) were 32% (95% CI 29–36) and 37% (95% CI 34–41) at 1 year and 21% (95% CI 18–24) and 22% (95% CI 19–26) at 5 years, respectively. In multivariate analysis, four risk factors had adverse impacts on DFS and OS: (1) age older than 35 years; (2) poor-risk cytogenetics; (3) t-AML not in remission or advanced t-MDS; and (4) donor other than an HLA-identical sibling or a partially or well-matched unrelated donor. Five-year survival for subjects with none, one, two, three, or four of these risk factors was 50% (95% CI 38–61), 26% (95% CI 20–31), 21% (95% CI 16–26), 10% (95% CI 5–15), and 4% (95% CI 0–16), respectively ($p < 0.001$).These data show that allogeneic HCT provides potentially curative therapy for t-MDS/t-AML as it does for de novo MDS. The major risk factors for inferior outcome appear to be disease stage and cytogenetics, together with patient age and donor HLA match or mismatch. Treatment of t-MDS/t-AML should include consideration of the likelihood of success of achieving remission with chemotherapy and, depending on the availability of an appropriate donor, the likelihood of a successful outcome with an allogeneic transplant approach. It is important to follow patients at risk for development of t-MDS/t-AML closely to identify the early development of this complication. Prompt transplantation should be considered after diagnosis of t-MDS/t-AML or, if possible, high-risk MDS, particularly in patients with low peripheral blast counts. It is clear, however, that innovative transplant strategies are needed to reduce the high risks of relapse and non-relapse mortality.

Prediction of risk of t-MDS/t-AML

Because of the poor prognosis associated with t-MDS/t-AML, there is interest in identifying predictors or early biomarkers of risk, to decrease the morbidity associated with this disease. Assessment of risk of t-MDS/t-AML after autologous HCT is complicated by the lack of a single underlying genetic abnormality. The development of t-MDS/t-AML appears to require the acquisition of more than one mutation. Moreover, t-MDS/t-AML is a heterogeneous disorder with multiple subtypes characterized by different genetic abnormalities. Therefore, the identification of a single genetic abnormality may not necessarily have predictive value for development of t-MDS/t-AML. Identification of early biomarkers would allow the timely use of appropriate measures to treat the disorder, such as reduced-intensity conditioning (RIC) or other novel agents, rather than waiting for the t-MDS/t-AML to present in the clinically overt form, when the disease burden would require higher-intensity therapy, with a greater risk of resultant morbidity. In fact, identification of patients at high risk for t-MDS/t-AML prior to transplantation would allow treatment strategies other than autologous transplantation – such as reduced-intensity allogeneic transplantation – to be considered for such patients to avoid the risk of t-MDS/t-AML.

Standard cytogenetics and FISH

Abnormal clones are frequently detected on cytogenetic analysis after autologous HCT for lymphoma. Traweek et al. [88]. reported the risk of developing a clonal cytogenetic abnormality typical of MDS to be 9% at 3 years. Five of 10 patients with the abnormal clone developed t-MDS. Stone [89] reported that 50% of sporadically tested post-transplant patients who were hematologically normal had clonal cytogenetic abnormalities. However, less than 30% of these patients developed t-MDS [21]. Evaluation by FISH may enhance sensitivity of detection of chromosomal abnormalities. Significant levels of clonally abnormal cells were detected by FISH prior to high-dose therapy in samples obtained from 20 of 20 patients who developed t-MDS/t-AML, but only in three of 24 patients who did not develop t-MDS/t-AML [26]. However, this technique is locus specific and requires prior selection of markers for analysis and the predictive value of clonal cytogenetic abnormalities for subsequent development of t-MDS/t-AML needs to be studied in a prospective fashion.

Polymerase chain reaction (PCR) assays for point mutations

Mutations in genes such as *MLL* or *AML1* or gene rearrangements involving the 11q23 gene may be useful markers for risk of subsequent t-MDS/t-AML. This method is highly sensitive, but is locus specific, and the specificity and predictive value of such assays are unknown at present. This test may be most helpful if performed using quantitative techniques that would allow assessment of increasing levels of abnormality [21].

Gene expression analysis

Gene expression microarray analysis of PBSC CD34$^+$ cells from patients who developed t-MDS after aHCT for HL or NHL and control subjects who did not develop t-MDS was used to derive a cross-validated t-MDS gene signature. This 38-gene signature when applied to an independent test set of patients who developed t-MDS after autologous HCT for NHL or HL, and matched controls correctly classified 14 of 16 subjects who developed t-MDS/t-AML, and 19 of 20 subjects who did not. Clonal abnormalities characteristic of t-MDS/t-AML were not seen on cytogenetic analysis of bone marrow samples obtained prior to autologous HCT, nor were they seen in FISH analysis of PBSC CD34$^+$ cells, indicating that the gene expression profile of cytogenetically normal hematopoietic cells can potentially identify patients at risk for t-MDS/t-AML post-aHCT.

Reducing risk of t-MDS/t-AML after autologous HCT

It is possible to consider potential strategies to reduce the risk of t-MDS/t-AML, based on our understanding of the risk factors and pathogenesis of t-MDS/t-AML. Such strategies may include minimizing pre-transplantation cytotoxic exposure, possibly by bringing high-risk patients to HCT earlier in the course of disease, prior to exposure to multiple treatment regimens. Alteration in autologous hematopoietic cell procurement regimens and the conditioning regimens could be considered to eliminate factors associated with increased risk of this complication. Standardized screening of patients in the immediate pre-HCT period with marrow pathology and cytogenetics could potentially help identify high-risk populations that would then benefit from an allogeneic rather than autologous HCT. If strategies to develop predictors for patients at high risk prior to HCT are realized, alternative treatment approaches such as allogeneic transplantation or non-transplant modalities may be worth considering for patients identified as being at increased risk of this complication. Finally, strategies for chemoprevention may be worth exploring in this population. While each of these risk reduction strategies holds validity, perhaps the one with the highest yield will be identifying patients at the highest risk of developing t-MDS/t-AML and minimizing leukemogenic exposures in that populations. Finally, the primary goal should be optimizing management of primary disease while attempting to reduce the risk of complications such as t-MDS/t-AML.

Lymphomas

Post-transplantation lymphoproliferative disorder

Lymphoproliferative disorders are the most common SMN in the first year after allogeneic T-cell-depleted HCT. Most of these cases are related to a compromised immune status and EBV infection. A large majority of the post-transplantation lymphoproliferative disorders (PTLDs) have a B-cell origin, although some T-cell PTLDs have been described.

B-cell PTLD

B-cell PTLD is a clinically and morphologically heterogeneous group of diseases. B-cell PTLD usually develops within the first 6 months after HCT, with most of the events occurring within the first 3 months. The cumulative incidence of PTLD has been reported to range from 1.0 to 2.0% at 10 years [2,90]. The incidence is highest in the first 5 months after HCT (120 cases per 10,000 per year), with a steep decline thereafter to fewer than five cases per 10,000 per year among HCT recipients surviving 1 year or longer.

Risk factors for B-cell PTLD

Risk factors found to be independently associated with an increased risk of PTLD include in vitro T-cell depletion of the donor marrow, unrelated or HLA-mismatched related donor, use of antithymocyte globulin or anti-CD3 monoclonal antibody for acute GVHD prophylaxis or in the preparative regimen, TBI, and primary immunodeficiency (Table 104.3) [2,91]. Patients transplanted for congenital immunodeficiency are at a particularly high risk for PTLD, because of both the underlying immunodeficiency and the use of T-cell

Table 104.3 Magnitude of risk and populations at increased of lymphoproliferative disorders after hematopoietic cell transplantation

Study	Study design	Sample size/ number of SMNs	Primary diagnoses; type of HCT	Magnitude of risk and risk factors
Landgren et al. [132]	Retrospective cohort study	26,901/127 PTLD	Hematologic malignancies and severe aplastic anemia Allogeneic HCT	T-cell depletion, use of ATG, unrelated donor HLA-mismatched grafts Cumulative risk increased to 8.1% with more than three risk factors
Curtis et al. [90]	Retrospective cohort study	18,014/78 PTLD	Hematologic malignancies Allogeneic HCT	Cumulative incidence 1% at 10 years Unrelated donor HCT, T-cell depletion, use of ATG, use of anti-CD3 monoclonal antibody

depletion of the donor graft [2,90,92]. Moreover, the risk of PTLD also depends on the method of T-cell depletion, being considerably higher where specific monoclonal antibodies are used for T-cell depletion (11–25%) rather than in patients where techniques removing both T- and B-lymphocytes, such as soybean agglutinin or alemtuzumab (<1%), are used [90]. However, the incidence of PTLD is higher in the latter group (6–18%) after exposure to immunosuppressive therapy such as steroids or antithymocyte globulins. The use of RIC coupled with highly immunosuppressive therapy needs close observation for the development of PTLD [93].

Pathogenesis of B-cell PTLD

B-cell PTLD is commonly associated with T-cell dysfunction, occurs in the presence of EBV infection, and is thought to develop because of a combination of depressed EBV-specific cellular immunity and the inherent transforming capacities of EBV. EBV is a ubiquitous herpesvirus that infects 95% of individuals by adulthood (see Chapter 90). The virus persists as a latent infection in B-lymphocytes, where reactivation and replication occur intermittently [94]. The latent membrane protein-1 is one of the EBV-encoded proteins believed to have an important role in B-cell immortalization by inducing the expression of *bcl-2*, which inhibits programmed death of the infected cells. *LMP-1* is also considered to be an oncogene and deletions near the 3′-end of the *LMP-1* gene, in a region that affects the half-life of the LMP-1 protein, have been reported in some lymphoproliferative disorders [95]. Infection of B cells by EBV also induces high levels of cytokines such as interleukin (IL)-1, IL-5, IL-6, IL-10, CD23, and tumor necrosis factor. Some of these factors have been shown to act as autocrine growth factors, stimulating the proliferation of EBV-transformed B cells and inhibiting their susceptibility to apoptosis.

Studies exploring susceptibility to EBV–PTLD have shown that cytotoxic T-lymphocyte precursor frequencies are low at 3 months after allogeneic HCT, but appear to normalize at 9–12 months, thus correlating with the period when B-cell PTLD is most frequently observed. Moreover, the EBV-specific cytotoxic T-lymphocytes home preferentially and induce selective regression of autologous EBV-induced B-cell lymphoproliferative lesions in xenografted severe combined immunodeficiency syndrome (SCID) mice [96]. These studies have formed the basis for clinical trials using adoptive transfer of EBV-specific cytotoxic T-lymphocytes [97]. The studies demonstrated long-term persistence of gene-marked EBV-specific cytotoxic T-lymphocytes in vivo, which not only restore cellular immunity against EBV but also provide a population of cytotoxic T-lymphocyte precursors that respond to in vivo and ex vivo challenges with the virus for as long as 18 months [98]. These studies have demonstrated that a combination of granulocyte–macrophage colony-stimulating factor and low-dose IL-2 therapy can prevent the immunodeficiency that leads to fatal EBV lymphoproliferative disease in xenografted SCID mice depleted of murine natural killer cells, and thus support a critical role for several human cellular subsets in mediating this protective effect.

Prediction of risk of B-cell PTLD

Quantitative competitive PCR has been demonstrated to be an effective technique in allowing frequent monitoring of the DNA load to predict the development of PTLD. Rapid increases in peripheral blood EBV DNA load predicted PTLD [99]. EBV-specific T-lymphocytes can be monitored through tetramer technology, which allows the detection of small quantities of antigen-specific T cells. Thus, it has been demonstrated that EBV-specific CD8 T cells are rapidly established following unmanipulated matched sibling allogeneic HCT, and HLA class I tetramers complexed with viral peptides can provide direct and rapid assessment of pathogen-specific immunity.

Treatment of B-cell PTLD

Patients considered to be at an increased risk for development of PTLD (primary immunodeficiency, HLA-mismatched HCT, and GVHD prophylaxis with T-cell depletion) should be monitored closely, so that appropriate therapy can be instituted early, prior to the development of overt disease. Therapeutic approaches that have been used include interferon-α, B-cell-specific monoclonal antibodies, and cellular therapy.

Anti-CD20 monoclonal antibody (rituximab) is effective in the treatment of PTLD [100]. The drug is well tolerated by all age groups and is more efficacious in patients without mass lesions. This observation forms the basis for recommendations to initiate treatment at an early stage, based on increasing EBV load, and before the development of lymphomatous lesions, or even before evidence of transformation. EBV-associated lymphoproliferative disorder developing after HCT has been shown to result from T-cell dysfunction. Reconstitution of "at-risk" patients with EBV-specific cytotoxic T-lymphocyte lines that have been reactivated and expanded in vitro should prevent the development of PTLD or treat pre-existing disease. The cytotoxic T-lymphocyte-reconstituted cellular immune responses to EBV have been shown to persist for up to 80 months. Cytotoxic T-cell therapy has been shown to be efficacious in controlling PTLD, with a decrease in the EBV DNA concentrations, and remission of clinical signs and symptoms [101].

Thus, over the past few years, the administration of in vitro-generated EBV-specific cytotoxic T cells or anti-B-cell monoclonal antibodies has provided an effective option for the prophylaxis or treatment of PTLD. Advances in quantitative PCR-based assays allow both the precise measurement of EBV load in peripheral blood samples and the identification of high-risk patients for early initiation of therapy. Patients should be monitored weekly by quantitative competitive PCR because viral load is a significant predictor of PTLD. Prevention of EBV PTLD by preemptive therapy based on molecular monitoring of EBV load may be used to decrease the occurrence of PTLD. Preemptive therapy with a single dose of rituximab has been reported to lead to the prevention of PTLD, and was first demonstrated by van Esser et al. [102]. The cut-off value of over 1000 EBV genome copies in 10^5 peripheral blood mononuclear cells demonstrates a sensitivity and specificity of 100% and a positive and negative predictive value of 1.00 [103].

Outcome of B-cell PTLD

Before the current methods of anti-EBV therapy were introduced, the mortality from EBV–PTLD was >80%. Preemptive use of rituximab and EBV-cytotoxic T-lymphocytes significantly reduced the risk of death due to EBV–PTLD in HCT recipients, with survival rates of 89.7 and 94.1%, respectively. Therapy of established PTLD also reduced the risk of fatal outcomes. However, the overall success rates were lower than after preemptive therapy, reaching 63 and 88.2% of total EBV–DNA clearance with rituximab and cytotoxic T-lymphocyte therapy, respectively. A reduction of immunosuppression and/or donor lymphocyte infusion might also reduce the risk of death due to EBV–PTLD. The responses to these modalities can be estimated to be 56.6 and 41%, respectively.

T-cell lymphoproliferative disorders

A few cases of T-cell lymphoproliferative disorders have been reported after HCT [104]. There is no association with EBV, human T-cell lymphotropic virus-1, human immunodeficiency virus or human herpesvirus 6. The T-cell lymphoproliferative disorders tend to occur much later than the EBV-associated B-cell PTLD.

Late-onset lymphoma

Late-occurring lymphomas represent an entity that is distinct from the early-occurring B-cell PTLD. In a large study of 18,000 HCT recipients, the only risk factor associated with the development of the late-occurring lymphoma was extensive chronic GVHD [90]. HL developing among HCT recipients has also been described. [105]. Most of the reported cases were of the mixed cellularity subtype, and most of the cases contained the EBV genome. These cases differed from the EBV-associated PTLD by the absence of risk factors commonly associated with EBV-associated PTLD, by a later onset (>2.5 years), and by a relatively good prognosis. The increased incidence of HL among HCT recipients could possibly be explained by exposure to EBV and overstimulation of cell-mediated immunity.

Solid tumors

Solid tumors have been described after HCT. The reported cumulative incidence of solid tumors following allogeneic HCT ranges from 1.2 to 1.6% at 5 years, from 2.2 to 6.1% at 10 years and from 3.8 to 14.9% at 15 years post-HCT [3,106,107]. There is no plateau in the incidence rate. Compared with an age- and sex-matched general population, the magnitude of increased risk of solid tumors is twofold [3]. Solid tumors reported in excess among HCT recipients are those typically associated with exposure to radiation therapy, and include melanoma, cancers of the oral cavity and salivary glands, brain, liver, uterine cervix, thyroid, breast, bone, and connective tissue. The risk of solid tumors increases sharply over time [106]. TBI is associated with an increased risk of solid tumors. The risk of solid tumors increases with the dose of radiation compared with those who did not receive radiation therapy (Table 104.4); the risk is 3–4 times elevated at the highest dose levels [107]. The risk of developing a non-squamous cell carcinoma following TBI is typically dependent on age at exposure. Among patients irradiated at ages under 30 years, the relative risk of non-squamous cell carcinoma was nine times that for non-irradiated patients, while the comparable risk for older patients was 1.1 [3]. Majhail et al. evaluated the risk of solid SMNs after HCT using high-dose busulfan–cyclophosphamide conditioning in 4318 recipients of allogeneic HCT for AML or chronic myelogenous leukemia (CML) [108]. The cumulative incidence of solid cancers at 5 and 10 years after HCT was 0.6 and 1.2% among AML and 0.9 and 2.4% among CML patients, respectively. In comparison with the general population, HCT survivors were at a 1.4-fold increased risk. Significantly increased risks were observed for tumors of the oral cavity, esophagus,

Table 104.4 Magnitude of risk and populations at increased of solid tumors after hematopoietic cell transplantation

Study	Study design	Sample size/ number of SMNs	Primary diagnoses; type of HCT	Magnitude of risk and risk factors
Curtis et al. [107]	Retrospective cohort	19, 229/80 solid malignancies	Allogeneic HCT	2.7-fold increased risk of solid malignancies compared with the general population Cumulative incidence: 6.7% at 15 years; younger age at HCT associated with increased risk of solid malignancies; chronic GVHD and male gender associated with increased risk of squamous cell carcinoma
Bhatia et al. [106]	Retrospective cohort study	2129/29 solid malignancies	Hematologic malignancies Autologous and allogeneic HCT	2-fold increased risk compared with general population Cumulative probability: 6.1% at 10 years
Shimada et al. [133]	Retrospective cohort study	809/19 solid malignancies	All malignancies Autologous and allogeneic HCT	2.8-fold increased risk Cumulative incidence: 4.2% at 10 years Extensive chronic GVHD and older age were associated with increased risk
Gallagher and Forrest [134]	Retrospective cohort study	926/28 solid malignancies	Hematologic malignancies Allogeneic HCT	10-year cumulative incidence: 3.1% 1.85-fold increased risk compared with general population Older age at HCT and female donor associated with increased risk
Socié et al. [135]	Retrospective cohort	147/4 solid tumors	Severe aplastic anemia/ allogeneic HCT	Cumulative probability: 22% at 8 years
Socié et al. [91]	Retrospective cohort	3182/25 solid tumors; 20 PTLD	Acute leukemia in childhood	Cumulative risk of solid tumors: 11% at 15 years; Age <5 years at HCT; TBI was associated with increased risk of solid tumors; chronic GVHD associated with decreased risk Chronic GVHD, unrelated donor HCT, T-cell-depleted graft, use of ATG associated with increased risk of PTLD
Majhail et al. [108]	Retrospective cohort	4318/66 solid cancers	Acute myeloid leukemia Chronic myelogenous leukemia Allogeneic (matched related and unrelated) HCT	Cumulative incidence: 1.2% at 10 years 1.4-fold increased risk compared with general population Chronic GVHD associated with increased risk, especially oral cavity
Rizzo et al. [3]	Retrospective cohort	28,874/189 solid malignancies	All malignancies/allogeneic HCT	2.1-fold increased risk Age at exposure to TBI <30 years associated with 9-fold increased risk of non-squamous cell carcinoma Chronic GVHD and male gender associated with risk of squamous cell carcinoma

Table 104.5 Magnitude of risk and populations at increased of specific SMNs after hematopoietic cell transplantation

Study	Study design	Sample size/number of SMNs	Primary diagnoses; type of HCT	Magnitude of risk and risk factors
Rowlings et al. [105]	Retrospective cohort	18,531/8 Hodgkin lymphoma	Hematologic malignancies and severe aplastic anemia Allogeneic HCT	6.2-fold increased risk Grade 2–4 acute GVHD, treatment for chronic GVHD
Leisenring et al. [109]	Retrospective cohort study design	4180/237 non-melanoma skin cancer	All malignancies and metabolic disorders Allogeneic HCT	20-year cumulative incidence: BCC 6.5%, SCC 3.4% TBI and younger age at irradiation, light skin color, chronic GVHD associated with BCC Acute and chronic GVHD associated with SCC
Curtis et al. [121]	Case–control	58 squamous cell and 125 basal cell carcinomas 501 matched controls	Hematologic malignancies, severe aplastic anemia, hemoglobinopathies Allogeneic (matched related and unrelated) HCT	Prolonged and severe chronic GVHD and its therapy (azathioprine, corticosteroids, cyclosporine) were associated with squamous cell carcinomas
Schwartz et al. [110]	Retrospective cohort	6,306/282 Basal cell carcinomas	Hematologic malignancies; severe aplastic anemia; Autologous, matched related and unrelated donor HCT	TBI exposure; youngest age at HCT; increasing attained age; whites; more recent birth cohorts
Friedman et al. [111]	Retrospective cohort	3337 females/52 breast cancers	Hematologic malignancies Allogeneic HCT	Cumulative incidence: 11% at 25 years Longer time since HCT, use of TBI, younger age at HCT
Cohen et al. [112]	Retrospective cohort	78,914/32 thyroid cancer	All malignancies and severe aplastic anemia Autologous and allogeneic	3.26-fold increased risk Young age at HCT, irradiation, female gender, chronic GVHD

lung, soft tissue, and brain. Chronic GVHD was an independent risk factor for all solid cancers, especially cancers of the oral cavity. Although most studies have focused on allogeneic HCT recipients, there is emerging evidence for an increased incidence of new solid malignancies among patients conditioned with TBI and receiving autologous HCT [22].

The magnitude of risk and associated risk factors for some of the more commonly occurring second solid tumors among HCT recipients are detailed in Table 104.5 and summarized below.

Skin cancer: The 20-year cumulative incidence of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) are reported to be 6.5 and 3.4% respectively, after allogeneic HCT [109]. TBI is a risk factor of BCC, particularly among patients younger than 18 years old at HCT. Acute GVHD increases the risk of SCC; chronic GVHD increases the risk of BCC and SCC. Schwartz et al. demonstrated that the risk of BCC associated with radiation is highest for the youngest ages at exposure, with relative risks exceeding 20 for those transplanted at ages less than 10 years, and decreasing with increasing age at exposure until age 40 years, above which no excess risk was identified [110]. Rizzo et al. demonstrated that chronic GVHD and male sex are the main determinants for risk of SCC [3].

Breast cancer: The 25-year cumulative incidence of breast cancer is reported to be 11% after allogeneic HCT [111]. Allogeneic HCT survivors are at a 2.2-fold increased risk of developing breast cancer compared with an age- and gender-matched general population. The median latency from HCT to diagnosis of breast cancer is 12.5 years. The incidence is higher among those exposed to TBI (17%) than among those who did not receive TBI (3%). The risk is increased among those exposed to TBI at a younger age.

Thyroid cancer: HCT recipients are at a 3.3-fold increased risk of thyroid cancer compared with an age- and gender-matched general population [112]. Age younger than 10 years at HCT, neck radiation, female gender, and chronic GVHD are associated with an increased risk of thyroid cancer. Thyroid cancer develops after a latency of 8.5 years and is associated with an excellent outcome.

Pathogenesis of solid tumors after HCT

There is limited information about the pathogenesis of solid tumors after HCT. An interaction of cytotoxic therapy, genetic predisposition, viral infection, and GVHD, with the consequent antigenic stimulation and use of immunosuppressive therapy, all seem to have a role in the development of new solid tumors.

Radiogenic cancers generally have a long latent period, and the risk of such cancers is frequently high among patients undergoing irradiation at a young age. A large series reported an increased risk of brain and thyroid cancers after TBI as part of high-dose conditioning, although most of these patients had received cranial irradiation prior to transplantation [87]. The increased risk of thyroid, breast, brain, bone, and soft tissue cancers seen after HCT appear to be related to cumulative doses of radiation exposure, as a result of both the pre-transplant treatment regimen and the conditioning regimen used for transplant.

Immunologic alterations may predispose patients to SCC of the buccal cavity, particularly in view of the association with chronic GVHD [109]. Themeli et al. demonstrated that chronic tissue stress due to interaction of alloreactive donor cells with host epithelium after allogeneic HCT might cause genomic alterations [113]. They analyzed buccal samples obtained from 71 allogeneic HCT recipients for microsatellite instability (MSI). MSI was observed in 52% of the allogeneic HCT recipients, but was not observed among the 31 healthy individuals or autologous HCT recipients. There was a trend for increasing risk of MSI for patients who experienced severe GVHD. SMNs were diagnosed in 14% of the MSI$^+$ and 3% of the MSI$^-$ patients. In an in vitro model of mutation analysis, there was a significant induction of frameshift mutations and DNA strand breaks in HaCaT keratinocytes cocultured with mixed lymphocyte cultures (MLCs) but not after their exposure to interferon-γ, TNF-α, transforming growth factor-β, MLC supernatant, peripheral blood mononuclear cells (PBMCs) or phytohemagglutinin-stimulated PBMCs. These findings suggest a reactive oxygen species-mediated mechanism. These data suggest that alloreactions after allogeneic HCT might induce genomic alterations in the epithelium [113]. Khan et al. examined genomic instability in oral and nasal mucosal specimens from allogeneic HCT recipients. The comparison group included autologous HCT survivors, patients treated with conventional therapy, and healthy control subjects. Genomic instability was detected in 60% of the oral versus 4% of the nasal specimens in allogeneic HCT survivors, and in none of the individuals from the comparison group. In the oral specimens, genomic instability was significantly associated with a history of oral chronic GVHD, suggesting a possible mechanism for the development of SCC in the oral cavity and not the nasal cavity [114].

The increased risk of new solid tumors after HCT is thus likely related to pre-HCT radiation for treatment of primary disease, TBI used for conditioning, altered immune function in association with viral infections [hepatitis B virus, hepatitis C virus, or human papillomavirus (HPV)], and genomic instability related to chronic stress after allogeneic HCT.

Treatment of patients with solid tumors after HCT

Treatment strategies for patients developing solid tumors after transplantation are not well defined. With respect to outcome, small case series indicate both ends of the spectrum: favorable outcome [115] and also aggressive tumor growth and early relapse after standard therapy [116]. A comprehensive study of a large number of patients with second solid tumors will help determine the nature of these tumors and their outcomes compared with de novo tumors. Until then, patients with solid tumors developing after transplant should be treated with the best available therapy for that tumor, unless there is compelling evidence that they will not be able to tolerate that therapy.

Screening for subsequent malignant neoplasms in HCT survivors

There is paucity of data regarding the clinical details at presentation of SMNs, in particular the clinical stage. Theoretically, if screening practices resulted in subsequent cancers being diagnosed at an earlier stage at time of presentation, then treatment would be more successful and survival rates higher. Additionally, less aggressive treatment may be required resulting in less toxicity. The issues of who to screen, how to screen, and when to do it are all important but largely unanswered questions. For the pediatric survivor population, the Children's Oncology Group has developed comprehensive long-term follow-up guidelines that provide risk-adapted recommendations based on therapeutic exposures and that are supported by the best available published literature [117]. For the HCT survivors, screening recommendations must incorporate risks associated with pre-HCT therapy and also from the transplant conditioning therapy and other HCT-associated conditions such as chronic GVHD. Joint recommendations for screening and preventative practices for long-term survivors after HCT from the European Group for Blood and Marrow Transplantation, the Center for International Blood and Marrow Transplant Research, and the American Society of Blood and Marrow Transplant were published in 2006 [118]. This reference provides general guidance for SMN screening for HCT survivors but recommendations are limited to risk awareness counseling and clinical assessments. General recommendations for colorectal, breast and cervical cancer are provided but are for the most part based on guidelines for the general population. Screening guidelines developed for use in the general population [119,120] may or may not be sufficient or applicable for use in HCT survivors, given the modest increase in risk of solid SMNs overall. For some individuals, additional risk factors either pre-HCT (exposure to chest irradiation, cranial irradiation, alkylating agents, topoisomerase II inhibitors) or associated with HCT (TBI, chronic GVHD, duration of immunosuppression, T-cell depletion) may lead to elevated risks and patients at significantly increased risk need to be identified for tailored screening strategies.

Risk-reduction strategies

Although strategies aimed at altering therapeutic exposures (chemotherapy and irradiation) will most likely result in a reduction in the risk of subsequent malignancies in some patients, it is unlikely that these exposures are the only factors that convey risk. In HCT recipients, the risk of SMNs is associated with duration of immunosuppression and also to chronic GVHD (likely from ongoing immunosuppression as opposed to an impact of GVHD itself), hence delayed immune recovery or persistent immunodeficiency may also contribute to the risk of subsequent malignancy after HCT [121]. Efforts to prevent GVHD and to improve immune reconstitution after HCT may be an effective strategy to reduce the risk of subsequent malignancy.

There is increasing concern related to the risk of cancer and cancer death associated with obesity and a sedentary lifestyle [122]. Functional and performance limitations and lower levels of physical activity have been reported in HCT survivors, particularly in those who have chronic GVHD [123,124]. Obesity (as determined by body mass index) is uncommon in HCT survivors [125]; however, preliminary studies of body composition reveal that they have a high percentage of fat mass and a reduction in muscle mass. This state of sarcopenic obesity contributes to the development insulin resistance, hyperinsulinemia, and chronic inflammation; factors that have been implicated in the causal pathway of obesity-associated cancer risk [126]. Hence interventions recommended for the general population aimed at improving nutrition and maintaining a physically active lifestyle are likely of even greater significance for HCT survivors as preventative measures for development of SMNs. Finally, as the pathogenesis of SMNs becomes more clearly elucidated, screening for known genetic susceptibility to cancer could possibly be undertaken and alternative therapeutic options presented to the vulnerable subpopulation. These strategies, and also those encouraged for all, such as avoidance of tobacco and alcohol, use of sunscreen, and HPV vaccination, may help to reduce the risk of SMNs in HCT survivors. Additionally, providing education to our survivors in order to raise awareness of the risk of SMNs and also to the primary care community who will be involved with the long-term follow-up and screening of these individuals will be very important.

Conclusion

HCT offers curative therapy for many patients with otherwise incurable disease. Currently, 60,000 transplants are performed annually (see Chapter 1), and most patients who do not experience a recurrence of their underlying disease within 1–2 years of transplantation do well and lead productive lives [127,128]. However, some complications do occur, and among those that have been described after HCT, malignant diseases are of particular clinical concern, because an increasing numbers of patients are surviving the early phase after transplantation and remaining free of their original disease.

The incidence of post-transplant malignancies appears to be low, although reliable estimates of the overall risk will require much longer follow-up. Despite the lack of randomized studies, the benefit of HCT, as compared with conventional therapy alone, in certain clinical situations outweighs the risk of late SMNs. However, it is imperative to follow this population of HCT recipients closely in order to screen them for the development of SMNs, and thus decrease the morbidity and mortality associated with this complication. Longitudinal monitoring of patients at multiple time points (before, during, and after HCT) is required to evaluate risk factors, study the evolution of genetic lesions, and identify biomarkers for SMNs. Improved understanding of risk factors may allow future modification of pre-transplant and transplant-related therapeutic exposures to minimize the risk for these complications. A better understanding of the pathogenesis of SMNs will allow for more effective screening to identify patients at risk prior to the HCT procedure, and allow more effective monitoring to detect early evolution of the malignancy post-transplantation. This may, in turn, allow for improved therapeutic decision-making while evaluating patients for HCT, and early institution of treatments directed at preventing and treating SMNs in patients at risk after HCT.

CHAPTER 105

Neurologic Complications of Hematopoietic Cell Transplantation

Harry Openshaw and Bihong T. Chen
City of Hope National Medical Center, Duarte, CA, USA

Introduction

Neurologic complications occur frequently after hematopoietic cell transplantation (HCT). Published rates vary from 3% in an autologous transplant series to 44% in matched unrelated donor transplants [1,2]. An even higher incidence of 46% was reported in pediatric transplants in the early transplant years [3], compared with an incidence of 15.8% in pediatric transplants carried out in the 1990s [4]. The wide variations of incidences may be explained by differences in patients selected for transplantation and also different time intervals sampled and varying criteria used for retrospectively identifying neurologic complications. A single prospective study of 115 consecutive transplants in the early 1990s reported an incidence of 17% occurring in the first 3 months after transplant [5]. In another approach, an incidence of 24% was recently estimated by recording all brain imaging ordered in consecutive allogeneic transplant patients in the first 12 months after transplantation [6].

Whatever the incidence, neurologic complications clearly have serious consequences. Autopsy series of allogeneic transplant patients in 1973–1998 reported gross brain pathologic abnormalities in almost 50% of cases; and central nervous system (CNS) pathology such as intracranial hemorrhage, abscess, and CNS metastases was considered the major cause of death in 17% of those autopsied [7,8]. The expectation is that improved standards in transfusion support and infectious disease prophylaxis have reduced the incidence of serious cerebrovascular and infectious neurologic complications; however, in a recent study of brain imaging carried out in 2004–2007, 15% of patients with neurologic complications had intraparenchymal cerebrovascular disease or CNS infection. The highest mortality was in those patients with cerebrovascular complications (estimated 0.10 12-month overall survival) [6].

A practical approach to the transplant patient requires an understanding of which problems are most likely at different times of the transplant course. As indicated in Table 105.1, neurologic complications may occur at three stages: (a) from the conditioning agents used for marrow ablation, (b) during pancytopenia, or (c) from immunosuppressive therapies and graft-versus-host disease (GVHD) in allogeneic transplant recipients. It is important to understand the patient's pre-transplant neurologic status, particularly in patients heavily pretreated with neurotoxic chemotherapy, and how this may influence post-transplant complications. Experienced practitioners narrow down the differential diagnosis by taking into account the hematologic diagnosis, therapy given (pre-transplant chemotherapy, conditioning agents, immunosuppressants, and supportive care drugs), and the time interval after transplant. This chapter is organized according to standard disease categories as given in the first column of Table 105.1.

Infectious complications

The neurologic presentation of CNS infection in HCT recipients is usually an alteration in mental status, delirium, or depression of sensorium, often without meningeal signs or obvious lateralizing neurologic signs. A spinal fluid examination is indicated once a mass lesion has been excluded. For a suspected brain abscess, a stereotactic biopsy under appropriate platelet support usually is diagnostic. Antimicrobial prophylaxis early in the transplant course is particularly effective for Gram-negative organisms, and bacterial meningitis at this stage is now unusual. Also unusual, but still a risk, is bacterial meningitis in long-term survivors with chronic GVHD (cGVHD), including *Listeria monocytogenes* meningitis and meningitis due to penicillin-resistant *Streptococcus pneumoniae* [9].

Aspergillus species accounted for 30–50% of CNS infections in autopsy series and remain a major problem in HCT. Figure 105.1a shows a typical *Aspergillus* abscess. Less common is *Aspergillus* endarteritis presenting as a stroke (Figure 105.1b). *Candida albicans*, the other serious fungal pathogen encountered after transplantation, infects the CNS in only 3% of transplant patients with systemic candidemia [10], although *Candida* species abscesses accounted for 15% of the CNS infections in a large autopsy series from Brazil [8]. Chronic fungal meningitides, for example from *Cryptococcus neoformans,* a frequent complication of immunosuppression in other disease processes, is rarely encountered in HCT recipients. More common is CNS infection with the protozoan *Toxoplasma gondii* early after engraftment, particularly in patients who do not receive trimethoprim and sulfamethoxazole prophylaxis (Figure 105.1c and 1d).

Herpes simplex virus (HSV) type 1 reactivates and is shed in the oral secretions of 80% of seropositive patients during the first few weeks after HCT [11]. As described in Chapter 88, acyclovir prophylaxis prevents viral shedding and is now used routinely in transplant centers. Despite the high incidence of viral reactivation, the clinical diagnosis of herpes simplex encephalitis is rarely made in transplant recipients. In immunocompetent individuals, herpes encephalitis usually occurs without any sign of mucocutaneous lesions. The brain infection is focal in the medial temporal lobes, most often presenting with seizures and psychiatric symptoms.

Table 105.1 Neurologic complications of hematopoietic cell transplantation

	Conditioning	Pancytopenia	Graft-versus-host disease
Infectious		Bacterial meningitis Gram-negative sepsis	Fungal abscess Meningoencephalitis
Cerebrovascular		Intracranial bleed Thrombotic angiopathy	Septic embolism, mycotic aneurysm ← Ischemic stroke →
Metabolic		Sedative–hypnotic drugs Hepatic encephalopathy of SOS	Hypoxia of interstitial pneumonia Hepatic encephalopathy of GVHD Uremic encephalopathy
Toxic	Encephalopathy (BCNU, busulfan, ifosfamide) Neuropathy (VP-16, cisplatin, paclitaxel)	Calcineurin inhibitor neurotoxicity → Steroid toxicity → Leukoencephalopathy →	Thalidomide neuropathy
Immune-mediated			Polymyositis Myasthenia gravis Demyelinating polyneuropathy

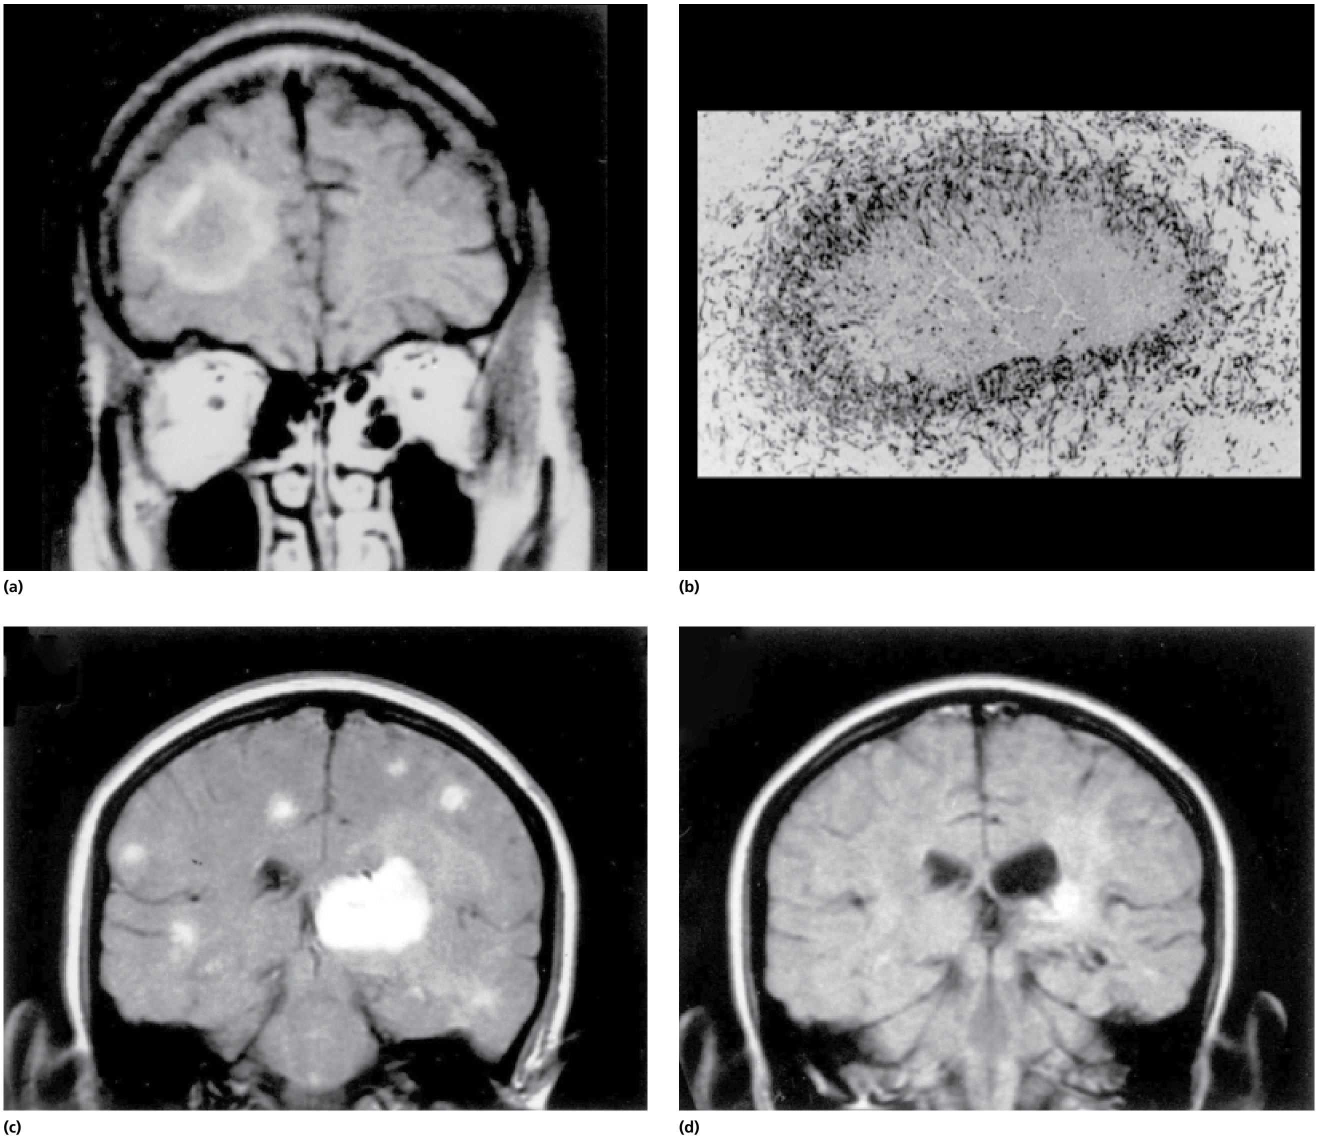

Figure 105.1 Fungal and parasitic CNS infections. (a) MRI of CNS *Aspergillus* infection. A 27-year-old man with Hodgkin disease developed pulmonary aspergillosis as documented by bronchoscopy 5 months after autologous transplantation. Gadolinium ring-enhanced lesions were documented in the right frontal lobe. CNS aspergillosis was confirmed at autopsy. (b) Post-mortem *Aspergillus* histopathology of a 45-year-old woman who developed a locked-in syndrome, rapidly evolving to coma and death 2 months after allogeneic transplantation for granulocytic sarcoma. Shown is a thrombosed branch of the basilar artery with mural invasion of the arterial wall by branching fungal hyphae (Gomori methanimine silver, ×100). (c) MRI of CNS *Toxoplasma gondii* infection. At 3.5 months after autologous transplantation for Hodgkin disease, a 21-year-old Hispanic woman developed right-sided upper motor neuron clumsiness with sensory symptoms, and MRI showed multiple gadolinium-enhancing lesions, the largest in the left parietotemporal area. (d) Neurologic recovery and almost complete resolution of the lesions on MRI occurred after 6 months of therapy with pyrimethamine and sulfadiazine.

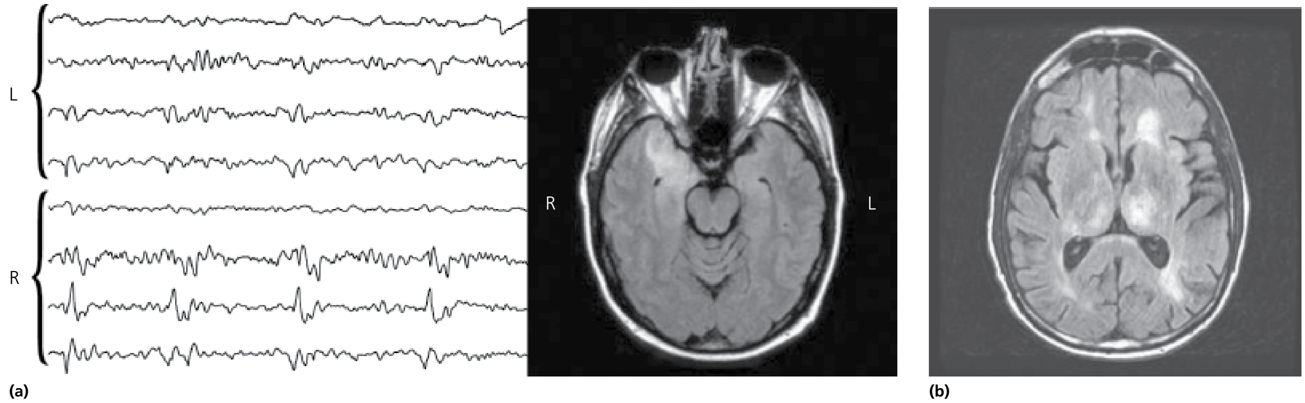

Figure 105.2 (a) Electroencephalogram (EEG) and brain MRI in herpes simplex encephalitis. A 46-year-old man whose acute myelogenous leukemia relapsed 8 months after autologous stem-cell transplant, and then underwent a non-myeloablative matched unrelated donor transplant with melphalan and fludarabine conditioning. On cyclosporine and prednisone for skin graft-versus-host disease, he developed abrupt confusion with visual agnosias 4 months after allogeneic transplantation. An EEG showed right-sided periodic sharp waves. Right frontotemporal increase signal developed on follow-up brain MRI FLAIR (fluid attenuated inversion recovery) sequence. The cerebrospinal fluid had 44 white blood cells/μL (87% lymphocytes) and 11 red blood cells/μL, and herpes simplex type 1 was cultured from the cerebrospinal fluid. Despite therapy with both acyclovir and foscarnet, there was neurologic progression with the patient developing an amnestic state, unable to form new memory traces. (b) Brain MRI (FLAIR sequence) in Epstein–Barr virus (EBV) encephalitis. A 63-year-old man 5 years after allogeneic transplant for AML with scleredermatous GVHD developed confusion, weakness with incoordination, and bilateral upper motor neuron signs. The cerebrospinal fluid had 39 white blood cells/μL (82% lymphocytes), and EBV sequences were detected in blood and cerebrospinal fluid. He was treated with rituximab and survived with neurologic disability.

Figure 105.2a shows an electroencephalogram (EEG) and magnetic resonance imaging (MRI) of a transplant patient who developed typical frontotemporal herpes simplex encephalitis. The EEG is helpful since periodic lateralized epileptiform discharges (as in Figure 105.2a) are characteristic for herpes encephalitis and may precede the MRI abnormality. Although HSV was cultured from the cerebrospinal fluid in the patient shown in Figure 105.2, viral cultures usually are negative in herpes encephalitis. Cerebrospinal fluid polymerase chain reaction (PCR) assay of HSV nucleic acid is helpful, but treatment should be initiated and continued in suspicious cases regardless of the PCR result.

Present about half as often as HSV, active varicella zoster virus (VZV) infection occurs later in the transplant course. The greatest incidence is during the fourth and fifth months after allogeneic transplantation (see Chapter 89). Facial nerve palsy and hearing loss can be associated with cranial zoster, arm weakness with cervical zoster, and neurogenic bladder with lumbosacral zoster. It is likely that a mild meningoencephalitis with or without pleocytosis and motor signs occurs fairly frequently in transplant patients with zoster; but the designation of varicella zoster encephalitis is usually reserved for the rare instances of diffuse encephalitis with a decrease in sensorium. Other serious manifestations include VZV vasculitis and retinal necrosis [12].

VZV and HSV have been implicated in peripheral facial weakness (Bell's palsy) in normal individuals without any skin or mucous membrane manifestations. Although a controlled study failed to show benefit of acyclovir added to prednisolone in normal individuals with Bell palsy [13], there has not been a similar study in transplant patients. It is probably prudent to start antiviral therapy with valacyclovir with or without corticosteroids in HCT patients who develop Bell palsy.

Recognized manifestations of cytomegalovirus (CMV) infection in transplant patients include pulmonary, hepatic, and gastrointestinal involvement. For reasons that are uncertain, CMV chorioretinitis, a very common problem in HIV-AIDS, is rarely diagnosed in HCT recipients [14]; similarly, CMV encephalitis is recognized at least histopathologically in HIV-AIDS but is rarely diagnosed or documented in marrow transplant recipients [15]. Fatal meningoencephalitis due to West Nile virus, adenovirus, and human herpesvirus type 6 (HHV6) have all been documented in marrow transplant recipients [16,17] and instances of HHV6 focal encephalitis in the medial temporal lobe, indistinguishable from HSV encephalitis, have been recognized (post-transplant acute limbic encephalitis). Use of conditioning regimens including alemtuzumab increases the risk of HHV6 encephalitis, even in patients receiving antiviral prophylaxis [18]. An example of Epstein–Barr virus (EBV) encephalitis in a transplant patient is presented in Figure 105.2b. Finally, progressive multifocal leukoencephalopathy, the slow virus infection caused by polyomavirus JC, has been reported in at least four patients after allogeneic HCT and 12 patients after autologous HCT [19,20]. PCR assays are now readily available for the detection of all of these viruses in cerebrospinal fluid, but particularly for progressive multifocal leukoencephalopathy (PML), brain biopsy may be necessary for diagnosis.

Cerebrovascular complications

Intracranial hemorrhage is most frequently associated with refractory thrombocytopenia and, except for subdural hematomas, large intracranial hemorrhages are usually fatal in HCT recipients. The characteristic clinical course of large supratentorial hemorrhages is abrupt onset of hemiparesis, or other neurologic deficit localized to the cerebral hemispheres, followed by rapid depression of the sensorium and development of brain-stem signs from transtentorial herniation (Figure 105.3a). A cerebellar hemorrhage is more difficult to recognize because of the subtlety of the initial signs – abnormalities of gait and eye movement – which then progress to gaze paresis and coma. Treatment of intracranial hemorrhage is the neurosurgical evacuation of the hematoma in those instances where this is feasible [21].

Subdural hematomas characteristically reduce the sensorium with no or mild lateralizing signs. Consequently, they can be

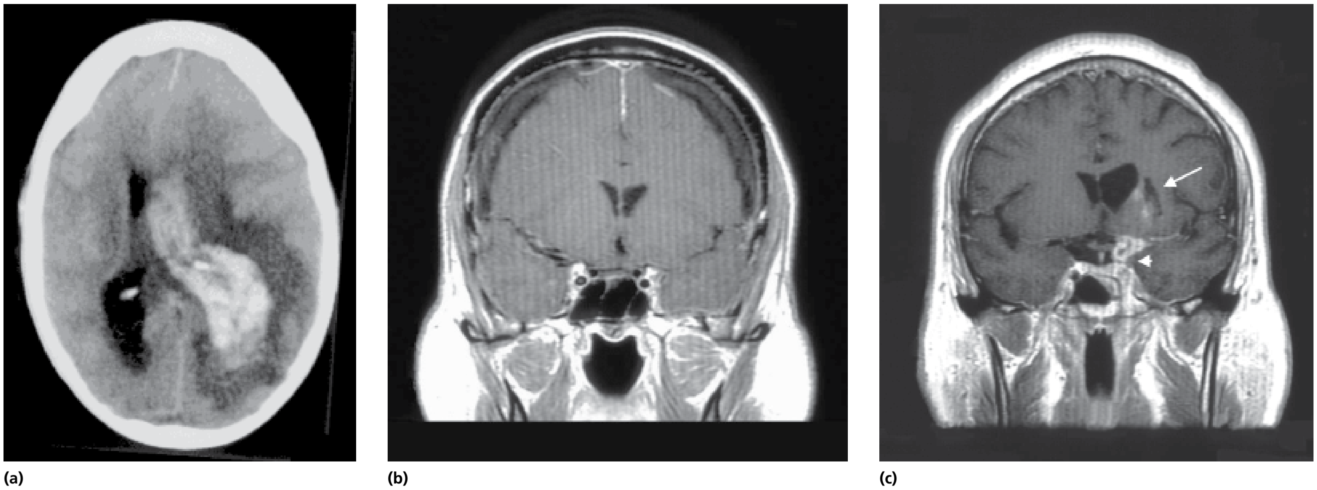

Figure 105.3 Cerebrovascular disease. (a) Brain CT of a fatal intracranial hemorrhage. A 34-year-old woman with biphenotypic leukemia underwent allogeneic bone marrow transplantation and 1.5 months later had a fatal massive left intraparenchymal hemorrhage with rupture into the left lateral ventricle. (b) Brain MRI of bilateral subdural hygromas resulting from multiple lumbar punctures and low cerebrospinal fluid pressure. A 48-year-old man with HIV-associated diffuse large cell lymphoma and leptomeningeal disease underwent three lumbar punctures for intrathecal therapy the week before high-dose BCNU and etoposide with autologous stem-cell transplantation. Two weeks after transplantation, there was confusion and reduced sensorium. The MRI showed bilateral subdural fluid collections, obliteration of cortical sulci, and balanced mass effect. After bilateral surgical drainage of the subdural hygromas, there was improvement in his sensorium. (c) Brain MRI of left sphenoid sinus infection with extension to the cavernous sinus (arrow head) and left hemisphere stroke (arrow). Sphenoid sinusitis developed in a 35-year-old man 5 months after autologous stem-cell transplantation for acute myelogenous leukemia. Despite repeated sphenoid surgeries, a left sixth nerve palsy developed followed by right hemiparesis and dysphasia. He was treated with amphotericin B and intraconazole for a presumed fungal infection. MRI shows sphenoid sinus opacification, a soft tissue mass within the left cavernous sinus occluding or narrowing the carotid artery, and an infarction involving the internal capsule, putamen, and head of caudate nucleus.

overlooked early in the course, particularly in patients who are sedated or encephalopathic for metabolic reasons. Non-hemorrhagic subdural fluid collections (hygromas) may develop over the cerebral convexities in patients who have low cerebrospinal fluid pressure as a consequence of repeated lumbar punctures (e.g., patients with acute lymphoblastic leukemia undergoing intrathecal treatment or prophylaxis for CNS leukemia) [22,23]. An epidural lumbar blood patch may help decrease the headache and shorten the time for the hygroma to resolve. However, with or without the blood patch, the hygroma may increase in size, as shown in Figure 105.3b, and surgical drainage may be necessary even if bleeding into the hygroma can be avoided. With or without neurosurgery, this complication may seriously compromise treatment of the leukemia by delaying further intrathecal therapy and the date of HCT.

Ischemic strokes in transplant recipients may be embolic from endocarditis or thrombotic associated with a hypercoagulable state. Vasospasm leading to ischemic symptoms or stroke has been suspected in rare patients at the time of cryopreserved stem-cell transfusion [24]. An endarteritis associated with meningeal infection, particularly with *Aspergillus* species, may occur and be difficult to distinguish clinically from primary cerebrovascular disease (see Figure 105.1b). Bacterial or fungal sphenoid sinusitis in transplant patients may result in a major hemisphere stroke by extension of the infection to the carotid artery in the venous cavernous sinus (Figure 105.3c). It is important that patients with severe sphenoid sinus infections undergo surgery and receive appropriate antibiotic or antifungal therapy to prevent cavernous sinus syndrome.

Non-bacterial thrombotic endocarditis occurs in transplant patients as a consequence of a hypercoagulable state [25]. Chemotherapy-induced endothelial damage and circulating immune complexes may also be contributing factors. In an autopsy series of 91 allogeneic transplant patients, there was a single case of bacterial endocarditis (group D *Streptococcus*) with stroke and seven cases of non-bacterial thrombotic endocarditis, with two of these patients having ischemic strokes.

Thrombotic microangiopathy, recognized in 5–15% of allogeneic transplant patients, may cause transient hemiparesis and seizures. Etiology probably is from endothelial cell damage from conditioning therapy or calcineurin inhibitors; diagnosis often requires a high degree of suspicion, identifying fragmented red blood cells (RBCs) and elevated serum lactate dehydrogenase (LDH) in the context of renal or hepatic abnormalities; treatment involves discontinuing calcineurin inhibitors. Plasma exchange has not been proven effective in transplantation-associated thrombotic microangiopathy [26,27].

Metabolic complications

The characteristic clinical feature of metabolic encephalopathy is toxic delirium, usually without lateralizing neurologic signs and with normal brain imaging. In transplant patients, toxic delirium is most often from sepsis, but it is also frequently iatrogenic from sedative–hypnotic drugs or calcineurin inhibitors. Less common is toxic delirium associated with viral encephalitis. The differential diagnosis here is often difficult, especially since brain imaging abnormalities of encephalitis are often absent or subtle. Clinical features that prompt spinal fluid analysis for viral PCR analysis or initiation of antiviral therapy include headache and psychiatric symptoms early in the course, absence of asterexis or myoclonus (frequent signs of metabolic encephalopathy and calcineurin inhibitor toxicity), persistent fever on antibiotics, seizures, worsening level of consciousness off calcineurin inhibitors, and no laboratory abnormality to account for worsening encephalopathy.

Hypoxic encephalopathy, carrying the risk of permanent neurologic disability, may occur from interstitial pneumonia or from hypoxemia associated with RBC lysis of thrombotic microangiopathy. Hepatic encephalopathy may occur from liver involvement in GVHD or from fulminant hepatic failure in sinusoidal obstruction syndrome (SOS) [28] (see Chapter 94). Renal failure with resultant uremic encephalopathy has been attributed to nephrotoxic drugs including the calcineurin inhibitors, the renal glomerulopathy that is rarely seen as a manifestation of GVHD, radiation nephritis, and thrombotic microangiopathy. Hypomagnesemia, associated with calcineurin inhibitors or as a residual from cisplatin nephrotoxicity, may cause convulsions in addition to cramps and muscle weakness. Reduced sensorium and seizures may occur from hyponatremia associated with the syndrome of inappropriate antidiuretic hormone secretion in viral encephalitis and intracranial mass lesions.

The occurrence of a severe metabolic abnormality within the first 100 days after transplant carries a poor prognosis with higher 100-day non-relapse mortality and a lower overall 5-year survival [29]. Multiple organ failure in HCT patients, as in other critically ill patients, is a poorly understood but generally fatal entity. SOS of the liver or pulmonary failure after transplant may herald multiorgan failure, including CNS failure. About 50% of HCT patients who develop a decrease in a standardized bedside mental status instrument in the first month of transplant go on to develop pulmonary or hepatic involvement and almost two-thirds of these patients do not survive 100 days after transplant [30]. An argument has been advanced that regardless of the initial organ system involved, the course in these patients reflects a systemic inflammatory response, the so-called multiple-organ dysfunction syndrome (MODS) [31]. As such, a systemic rather than an organ-specific approach to therapy is needed and such an approach will depend on a better understanding of the pathophysiology and initiating events of MODS and how these may be affected by high-dose chemoradiation.

Because of the increased risk of sepsis and shock, neurologic complications of critical illness may occur in transplant patients [32]. Critical illness polyneuropathy (CIPN) is thought to occur from inadequate perfusion of peripheral nerves and is often associated with encephalopathy, multiorgan failure, and prolonged mechanical ventilation. It is a predominantly motor axonal neuropathy with moderate to severe neurologic deficit interfering with respiratory weaning [33]. Recovery may be partial and slow, with survivors usually requiring months before they can resume ambulation. Another complication that interferes with respiratory weaning and may be confused clinically is acute critical illness myopathy [34]. Coincidence of both CIPN and acute critical illness myopathy probably occurs particularly in patients with multiorgan failure who have received neuromuscular blocking agents and corticosteroids.

Neurologic manifestations of recurrent disease

About 9% of neurologic problems encountered in the first year after transplant can be attributed to recurrence of CNS disease [6]. Leptomeningeal recurrences typically present as motor or sensory signs in the distribution of spinal nerve roots or cranial nerves. Clinical manifestations of hydrocephalus also can occur form cerebrospinal fluid absorption block. Although computed tomography (CT) can be used to monitor hydrocephalus, brain imaging with MRI is generally required to show leptomeningeal abnormalities: either gadolinium enhancement or patchy increased signal in the leptomeninges on fluid attenuated inversion recovery (FLAIR) sequences (Figure 105.4a, b). These MRI abnormalities may be present without motor or sensory abnormalities of leptomeningeal disease, but they are often subtle or absent. Cerebrospinal fluid analysis is needed to exclude an infectious process and confirm abnormal cytology.

Less common then leptomeningeal disease, CNS recurrence can manifest as a parenchymal mass, as shown Figure 105.4c. These recurrences can produce headache from increased intracranial pressure and upper motor neuron weakness or other signs from parenchymal mass lesion. Brain imaging is helpful in the differential diagnosis of cerebrovascular or infectious etiology; but brain biopsy may be required for definitive diagnosis. To avoid confusion from corticosteroid lympholytic effects, effort is generally made to delay dexamethasone in patients who are to undergo such diagnostic biopsy.

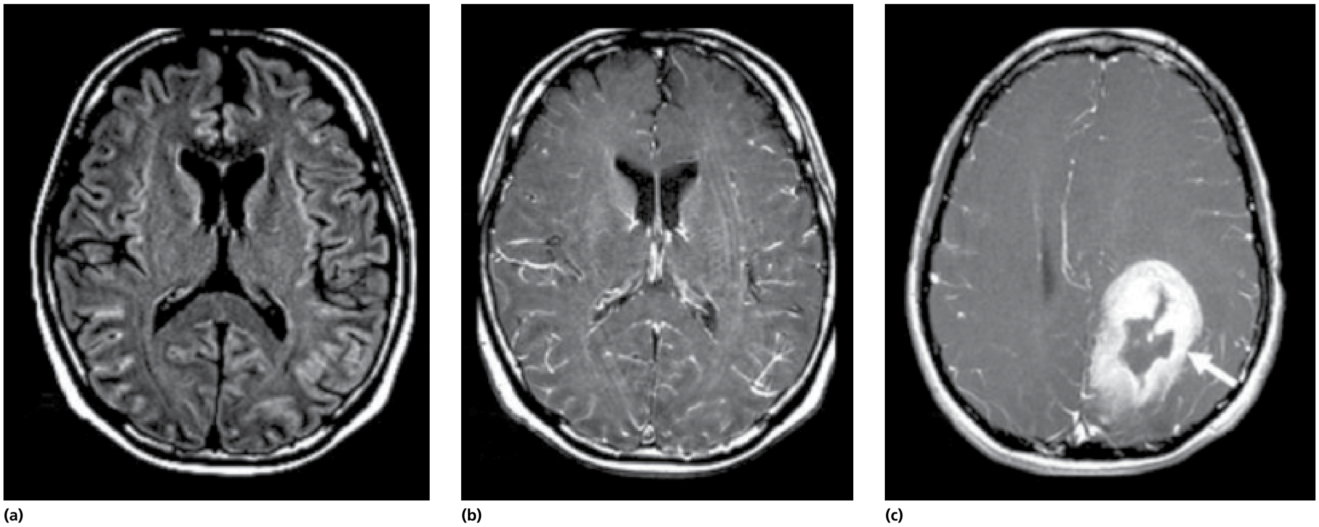

Figure 105.4 CNS recurrence of hematologic malignancy. (a, b) Brain MRI images of a 30-year-old woman with acute myelogenous leukemia who developed leptomeningeal disease 50 days after HCT. Axial FLAIR sequence (no contrast) shows abnormal hyperintensity diffusely throughout the cerebral sulci and along gyral surfaces (a), and the post-contrast T1-weighted image shows corresponding gadolinium enhancement (b). (c) Brain T1-weighted post-contrast image of a 17-year-old boy with altered mental status 105 days after HCT. The hemorrhagic enhancing mass was surgically removed and shown to be a chloroma.

Systemic recurrence of hematologic malignancy can also produce neurologic signs from a pressure effect on nerve root, plexus, or peripheral nerve. For example, bone marrow involvement in the mandible can result in numbness in the chin from involvement of the inferior alveolar nerve.

Immune-mediated complications of the central nervous system: a real entity?

In long-term HCT survivors, the incidence of MRI white matter abnormalities and abnormalities in neuropsychologic tests have been shown to correlate with cGVHD [35]. This correlation, however, probably results from complications of prolonged immunosuppression rather than a direct CNS affect of cGVHD.

A review of case reports and small series published between 1990 and 2007 found 18 reported cases of putative cGVHD of the CNS [36]. The time range of neurologic onset after HCT was 2–31 months (median 14.5 months) and the neurologic presentation was most consistent with angiitis and stroke in seven, immune-mediated encephalopathy in seven (four also with seizures), myelopathy in two, and progressive motor abnormalities in two. Etiologic factors other than GVHD, however, are possible in these patients. What would be helpful in evaluating these and subsequent cases is the establishment of diagnostic criteria which, if met in full or in part, would result in a consensus diagnosis of cGVHD of the CNS. Proposed criteria include (1) the presence of systemic cGVHD, (2) neurologic signs of white matter abnormality with no other explanation, (3) MRI abnormality corresponding to the neurologic signs, (4) abnormal cerebrospinal fluid studies (pleocytosis, elevated protein with relevant negative viral PCR studies), (5) brain biopsy or post-mortem examination abnormalities consistent with immune-mediated process, (6) and response to immunosuppressive therapy [36,37]. Cases that fall short may still be instances of cGVHD but more open to argument.

Immune-mediated abnormalities of the peripheral nervous system

Three immune-mediated diseases, all affecting the peripheral nervous system, can occur after HCT. Most common is polymyositis – a clinical syndrome characterized by proximal muscle weakness, elevated levels of creatine phosphokinase and other muscle enzymes, short-duration (myopathic) motor units on electromyography with signs of acute denervation (fibrillation potentials and positive sharp waves), and necrotic myofibers and mononuclear inflammatory cells on muscle biopsy. Less common is myasthenia gravis (MG), an immune-mediated disorder of the neuromuscular junction in which autoantibodies to the postsynaptic acetylcholine receptor produce a characteristic clinical syndrome of ptosis and extraocular muscle weakness, most often with proximal limb and facial muscle weakness. Less well accepted as a complication of HCT is immune-mediated demyelinating polyneuropathy, a condition producing neuropathic weakness that can be severe, sensory loss, and nerve conduction slowing on electrophysiologic tests. It is not difficult to differentiate polymyositis from MG and polyneuropathy. A potential problem arises when mild polymyositis goes unrecognized and accounts for a slower than usual functional recovery from transplantation.

A review article reported polymyositis in 3% of 318 patients with cGVHD [38]. Onset of weakness occurred 7–24 months after transplantation, and all patients showed improved strength with reinstitution or an increase in the dose of prednisone. There are rare reports in which polymyositis was the sole manifestation of GVHD and there is a case report of polymyositis occurring after autologous transplantation [39]. Muscle cramps are common in polymyositis, but disabling muscle cramps occasionally occur as a new problem in post-transplant patients without other neurologic findings or metabolic abnormalities.

It is important to exclude infectious causes of polymyositis and to exclude the occasional patient with drug-induced myositis. Zidovudine (AZT) as well as the combination of lovastatin and cyclosporine (CSP) can cause an inflammatory myopathy, and a fatal case of rhabdomyolysis occurred after a CSP-associated seizure in a transplant patient [40]. Muscle weakness in a patient with GVHD may also be from autoimmune hyperthyroidism [41] or, much more commonly, from steroid myopathy. A common treatment dilemma is whether steroids should be increased as therapy for polymyositis or decreased because of presumptive steroid myopathy. Further testing should help in this situation because unlike polymyositis, patients with steroid or other endocrine myopathies have neither electromyographic evidence of denervation nor inflammatory cells in muscle biopsy specimens.

The prevalence of post-transplantation MG is lower than that of polymyositis. Only three of 1800 allogeneic transplant recipients (<0.5%.) have been diagnosed at Seattle, and there is a similar low prevalence at other centers [42], Onset tends to be later than with polymyositis. Most patients are diagnosed after immunosuppressant drugs to prevent cGVHD have been decreased or discontinued. Patients transplanted for aplastic anemia appear to have a greater risk for acquiring MG, and many post-transplant MG patients have antiplatelet, antismooth muscle, antimitochondrial, and antinuclear antibodies and also anti-acetylcholine receptor antibodies. Thymoma, present in about 15% of patients with idiopathic MG, has not been identified in post-transplantation MG. Unlike polymyositis, which usually is self-limited, post-transplant MG tends to be a chronic, albeit sometimes fluctuating, problem requiring anticholinesterase drugs to control symptoms. Alternate-day low-dose prednisone is generally adequate if immunosuppressants are required. Return to higher dose immunosuppressants or treatment with plasma exchange is generally not necessary or recommended. It may be important to avoid, or use with caution, in these patients drugs that affect neuromuscular transmission, including aminoglycoside antibiotics, certain cardiac antiarrhythmic agents such as procainamide, and parenteral magnesium.

Because of the known increased risk of Guillain–Barré syndrome in Hodgkin disease and other disorders with reduced cellular immunity [43], it is not surprising that Guillain Barré-like neuropathies occasionally occur in transplant recipients [44]. Compared with MG and polymyositis, there is a greater clinical heterogeneity in these patients and less certainty as to the pathogenesis. Most are demyelinating but some are severe axonal neuropathies. The prevalence has been estimated at only 1% of allogeneic transplantations [45], but these neuropathies produce considerable morbidity because the deficit is predominantly motor and because they may occur early after transplantation when patients are medically most vulnerable. Prior CMV or *Campylobacter jejuni* infection probably triggers some instances of severe demyelinating neuropathy after transplant [46], and calcineurin inhibitors have also been implicated in some patients [45]. Although the pathogenesis is uncertain, an immune mechanism is suspected, and the transplant physician may face the dilemma of increasing the existing immunosuppressant drugs or discontinuing or switching calcineurin inhibitors. GVHD is present in most but not all patients, and the neuropathy has been thought to correlate with the course of GVHD in some patients. Necessary for the diagnosis of demyelinating neuropathy is the electrophysiologic demonstration of nerve conduction slowing or conduction block. It may be helpful to document cerebrospinal fluid protein elevation and myelin breakdown with reactive macrophages on nerve biopsy. Treatment of dysimmune polyneuropathy in these patients has included plasmapheresis with variable success; prednisone, which is effective in non-transplant-associated chronic inflammatory demyelinating polyneuropathy (CIDP) and intravenous γ-globulin. There may be a need for caution in considering a transplant for hematologic malignancy in patients with a pre-existing inflammatory demyelinating neuropathy, since abrupt worsening after conditioning involving radiation therapy has been reported in rare patients [47].

Complications from the calcineurin inhibitors cyclosporine and tacrolimus

Calcineurin inhibitors (CSP and tacrolimus) cause more neurologic problems in transplant patients than any other class of drugs [48]. Complications are diverse. Essential tremor is almost always present, and headaches of a vascular quality occur in up to 20% of patients. Seizures and encephalopathy are the most common serious complications. Typically these seizures follow complaints of headache, increased tremulousness, mild confusion, asterixis, and sometimes visual symptoms. Although usually single and generalized, multiple and partial seizures may also occur and there may be transient post-seizure deficits such as cortical blindness and behavioral abnormality. Phenytoin has been used after seizures induced by calcineurin inhibitors but recently some transplant physicians have shifted to levetiracetam, an anticonvulsant that unlike phenytoin does not affect the hepatic metabolism of calcineurin inhibitors. Most clinicians continue anticonvulsants until high-dose calcineurin inhibitor therapy is no longer required.

Patients who are encephalopathic from calcineurin inhibitors usually have elevated blood pressure and often have low serum magnesium. They may have abnormalities on MRI with multifocal areas of signal hyperintensity, most often in the occipital lobe white matter and sometimes associated occipital blindness [49] (Figure 105.5a). These abnormalities identified on MRI T2 or FLAIR sequences are consistent with posterior reversible encephalopathy syndrome (PRES), which is seen most often in the non-transplant setting in malignant hypertension, alone or in association with eclampsia [50]. Although most scan abnormalities from calcineurin inhibitors show predominant white matter lesions, there can be mixed cortical and subcortical involvement, sometimes associated with punctate cortical gadolinium enhancement (Figure 105.5b,c) [51]. Cerebellar and brain-stem MRI lesions exceptionally occur and transient eye movement abnormalities have been reported from calcineurin inhibitors in HCT patients [52] (Figure 105.5d). In contrast, clinical findings of hemiparesis or hemisensory loss would be considered highly atypical for calcineurin inhibitor toxicity; such lateralizing motor or sensory signs usually suggest an ischemic insult or a cerebral mass lesion.

Calcineuron inhibitor neurotoxicity is less often detected by CT than MRI, but marked CT abnormalities can occur, as shown in Figure 105.5e. The reversibility of the CT abnormality on follow-up scans (Figure 105.5f) argues against cerebral infarction and for vasogenic edema. Damage to the vascular endothelium from chemotherapeutic drugs, breakdown of the blood–brain barrier from radiation, or from CSP itself , may all be contributing factors. CSP leads to the release of endothelins, vasoactive neuropeptides that have been implicated in cerebral vasospasm [53]. Endothelin release may be triggered by or may cause microangiopathic hemolytic anemia, a condition found by multivariate analysis to have the highest correlation with CSP toxicity [48]. Vasospasm, shown to be present on an MR angiogram [51], may explain involvement at junctions of major vessels (watershed areas) or at the distal distribution of major vessels, such as the occipital pole. Neuropathology of CSP toxicity is limited, but reports indicate edema or demyelination. There is a report of vasculitis attributed to tacrolimus in a liver transplant patient [54].

Although these vascular abnormalities are now well recognized, they probably do not account for all instances of serious calcineurin inhibitor neurotoxicity. Sometimes there is severe neurotoxicity with encephalopathy prolonged for days, to near-coma, yet the MRI is normal. In other instances, there is relatively mild encephalopathy but with MRI abnormalities on FLAIR or T_2 sequences. In animals, CSP has a direct neurotoxic effect, independent of alterations in blood pressure or renal function [55]. A cell culture study showed that CSP can induce neuronal apoptosis and selective oligodendrocyte death [56]. The mechanism probably involves inhibition of the phosphatase activity of calcineurin, the same mechanism whereby CSP inhibits T-cell proliferation. CSP is bound by serum lipoproteins, metabolized in the liver cytochrome P450 enzyme system, and excreted in bile. Blood levels may become elevated in patients with hyperbilirubinemia, GVHD of the liver, or sinusoidal obstruction syndrome [57]. Erythromycin, ketoconazole, and calcium channel blockers decrease hepatic metabolism of CSP, whereas phenytoin enhances hepatic metabolism [48,58,59]. Hypocholesterolemia is associated with an increase risk of CSP neurotoxicity [60], probably because of an increase in unbound CSP; and it is likely that the low cholesterol levels in liver disease account at least in part for the twofold greater prevalence of CSP neurotoxicity in liver transplant patients compared with HCT patients. CSP does not penetrate the blood–brain barrier well under normal conditions, but damage to the barrier by conditioning agents, particularly irradiation, may increase the penetration of calcineurin inhibitors. Despite clinical experience suggesting a direct toxic role of CSP, neurotoxicity does not always correlate with steady-state drug levels. It has been proposed that high peak levels (e.g. at times of intravenous use) may predispose to neurotoxicity [48].

A considerable degree of clinical judgment often goes into decisions on when to reduce or hold calcineurin inhibitors to prevent the more serious instances of neurotoxicity. Even mildly encephalopathic patients who have worsening asterixis or develop myoclonus should be considered for supplementary intravenous magnesium, temporary discontinuation of the calcineurin inhibitor regardless of the drug level, and possibly a loading dose of intravenous fosphenytoin or phenytoin. Clinical experience in HCT suggests that temporary discontinuation of calcineurin inhibitors and then restarting at a lower dose are usually successful in preventing worsening or recurrence of neurotoxicity. Switching from CSP to tacrolimus or vice versa is seldom necessary, and is not always successful in preventing recurrence of neurotoxicity.

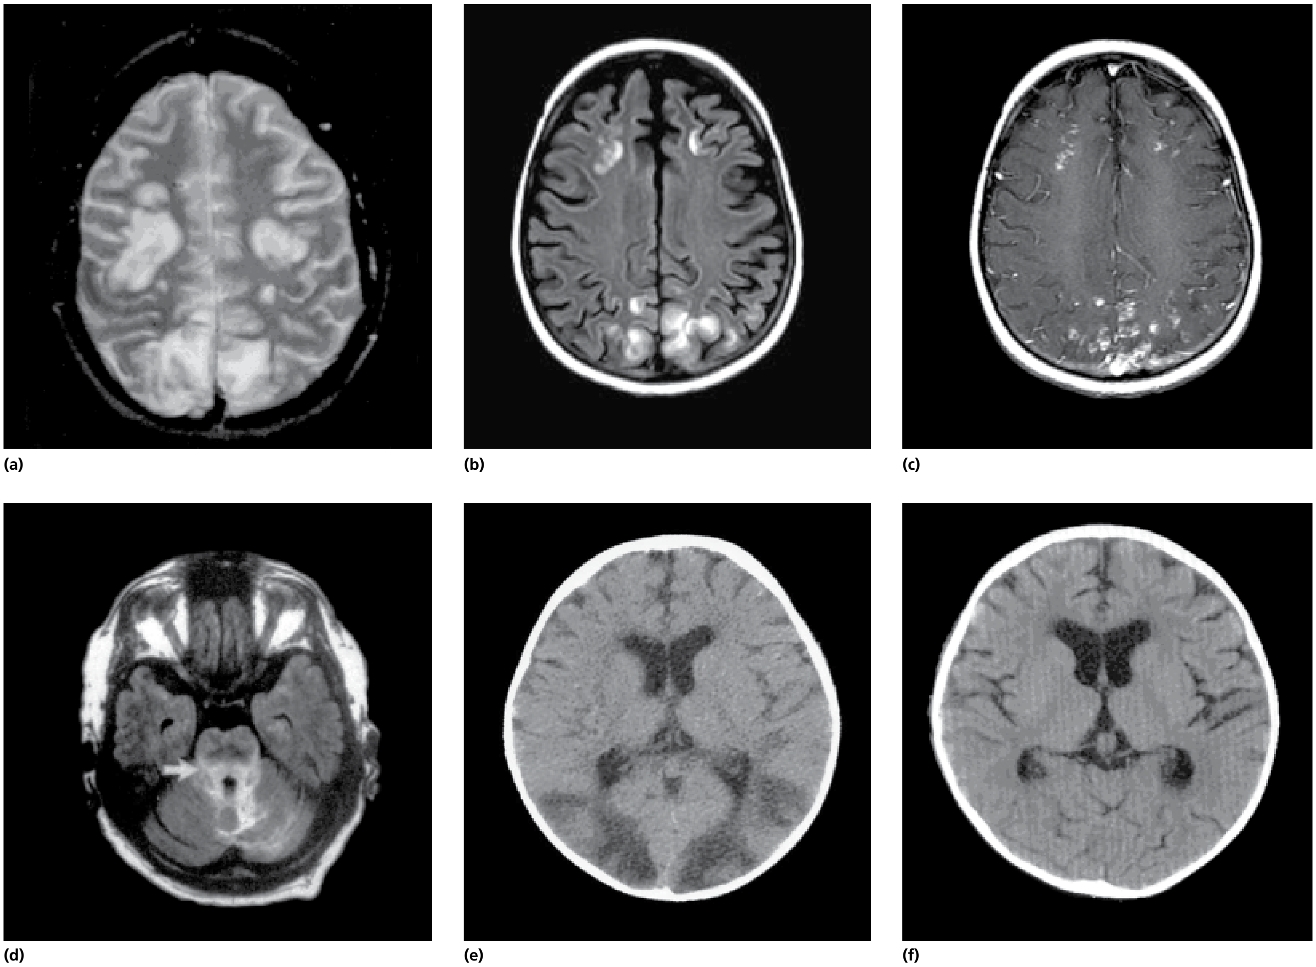

Figure 105.5 Calcineurin inhibitor neurotoxicity. (a) Brain MRI (T2 sequence) of a 20-year-old woman 5 weeks after allogeneic transplantation for chronic myeloid leukemia who developed abrupt onset of confusion and headache. Patches of bright signal on T_2-weighted images were present, especially in the parietal and occipital subcortical white matter. Later, a generalized seizure with encephalopathy occurred and CSP was stopped for 4 days and then restarted at a lower dose. Repeat MRI showed resolution of the lesions. (b, c) Brain MRI FLAIR sequence (b) and T1 sequence with gadolinium (c) in an 11-year-old girl with acute lymphoblastic leukemia on tacrolimus 4.5 months after cord blood transplant. (d) Brain MRI (FLAIR sequence) of a 50-year-old man who developed diplopia 2 months after allogeneic transplant for mantle cell lymphoma. The arrow shows signal abnormality included the area of the cranial nerve VI nucleus. Eye movements returned to normal 2 days after CSP was discontinued. (e) Brain CT in a 2-year-old girl with acute lymphoblastic leukemia and liver chronic GVHD who developed seizures and reduced sensorium 1 year after matched unrelated donor transplant. A follow-up scan (f) carried out 1 month later showed almost complete resolution of parieto-occipital edema. Source, panel (d): Openshaw 2001 [95]. Complications from other immunosuppressive drugs

A sense of wellbeing and even euphoria often accompanies the initiation of corticosteroid treatment. With continued administration, psychotic depression, mania, or delirium may occur [61]. This toxicity is often dose dependent, but when a reduction in steroid dose is not feasible, neuroleptic or antianxiety medications may be necessary. Proximal muscle weakness due to muscle protein catabolism is experienced by virtually all transplant patients who receive the equivalent of 40 mg of prednisone per day for more than 3 weeks [62]. Typical symptoms include difficulty arising from a chair and difficulty washing hair. Muscle cramps and tenderness occur less often with steroid myopathy than with polymyositis. Unlike polymyositis, serum creatine phosphokinase levels are normal or only slightly elevated in steroid myopathy, and electromyography often shows only slight abnormalities with myopathic motor units. Treatment consists of switching from the more myotoxic fluorinated steroids such as dexamethasone to non-fluorinated agents, such as prednisone or methylprednisolone, tapering the steroids when this is possible, and instituting daily physical therapy. Regular exercise during corticosteroid treatment may reduce the catabolic effect on muscle.

Symptoms of thalidomide peripheral neuropathy can begin after 2 months of therapy at 100 mg per day, the starting dose sometimes used for cGVHD [63] and within the dose range sometimes used for maintenance after autologous transplant for multiple myeloma (see Chapter 55). Lower-limb numbness and paresthesias occur, often accompanied by burning and hyperesthesia of the feet. With continued exposure, leg cramps and a stocking-glove pattern of sensory loss develop involving superficial sensation more than proprioception or vibration. Patients with severe neuropathy may have muscle weakness. An unusual feature compared with other toxic neuropathies is the preservation of deep tendon reflexes well into the course of the neuropathy. There may be mild elevation of cerebrospinal fluid protein, and nerve conduction tests and morphologic analysis indicate a large-fiber, "dying-back" sensory neuronopathy (i.e. initial degeneration in the distal region of the axon and progression of the degeneration proximally to the nerve cell body) [64]. The extent of neurologic recovery after discontinuation of thalidomide depends on the severity of the symptoms and possibly the patient's age and duration of exposure. Motor signs revert more readily and completely than sensory symptoms and, in some patients, distressing sensory complaints may be permanent [65].

Low-dose intravenous methotrexate (MTX), frequently used for GVHD prophylaxis, causes only occasional and minor neurotoxicity of headache, dizziness, and rarely seizures when given to patients with rheumatoid arthritis [66]. High-dose MTX (5 g/m^2 per cycle), used mainly for osteogenic sarcoma, can trigger transient leukoencephalopathy, similar in appearance to but usually more extensive than the MRI abnormalities seen with calcineurin inhibitors [67], and acute, transient CNS toxicity often with hemiparesis, occurs rarely after intathecal MTX. Much less often seen now in transplant patients is the delayed-onset, chronic, and often fatal leukoencephalopathy resulting usually from the combination of intrathecal MTX and whole-brain irradiation [68]. Neurologic signs usually within 4–5 months after transplant include dysarthria, ataxia, dysphasia, spasticity and upper motor neuron weakness, seizures, confusion, and a decrease in sensorium. Leukoencephalopathy with severe neurologic sequelae and death has also been attributed to amphotericin B following total body irradiation in a transplant recipient [69].

Complications from conditioning agents

Neurologic complications from chemotherapeutic drugs in the conditioning regimen include encephalopathy and seizures as acute self-limited complications and peripheral neuropathy as delayed, longer lasting complications. Busulfan (BU) and carmustine [1,3-bis(2-chloroethyl)-1-nitrosourea; BCNU] are common causes of encephalopathy, and etoposide and cisplatin are common causes of peripheral neuropathy. Granulocyte colony-stimulating factor (G-CSF) may exacerbate autoimmune activity during peripheral blood hematopoietic stem-cell mobilization of patients with multiple sclerosis [70]. Long-term disabilities of conditioning agents that may involve cognition and quality of life are discussed in Chapter 103 and the long-term risks of primary brain tumors in Chapter 104.

Before routine use of prophylactic anticonvulsants, generalized seizures occurred overall in about 10% of patients receiving high-dose BU (4 mg/kg/day for 4 days) [71]. BU readily crosses the blood–brain barrier, and it is presumed that seizures occur as a direct neurotoxic effect. Although myoclonic twitching may be seen shortly before or after the ictus, BU seizures usually are not focal and seldom are they multiple or complicated. Because phenytoin induces the metabolism of BU, levetiracetam or another enzyme non-inducer is probably preferable anticonvulsant prophylaxis, particularly if there is no attempt to adjust the BU dose based on blood levels. Anticonvulsant prophylaxis also has generally been used with high-dose BCNU. Headache with flushing and paresthesias around the lips have been reported during high-dose BCNU infusion [72].

Neurologic manifestations of ifosfamide toxicity include seizures, acute confusional state, mutism, and disordered sensorium. Rare instances of extrapyramidal toxicities with opisthotonos have also been noted [73]. The toxicity may be related to a buildup of a chloral hydrate-like compound, chloroacetaldehyde, a major breakdown product of ifosfamide. There have been reports of treatment with methylene blue [74]. Fludarabine used now in reduced-intensity conditioning may cause encephalopathy and rarely progressive neurologic disability with CNS demyelination [75]. Seizures and transient encephalopathy have been observed with high-dose cytarabine (cytosine arabinosiude; Ara-C), although the most common neurologic problem is cerebellar dysfunction, occurring in 10% and leaving permanent ataxia from Purkinje cell dropout in 3% of treated patients [76] . There have also been a few published cases of peripheral neuropathy with high dose Ara-C, including patients with clinical and electrophysiologic features of acute demyelinating polyneuropathy consistent with the diagnosis of Guillain–Barré syndrome [77].

A sensory axonal neuropathy with mild or no motor disability developed in 4% of autologous transplant patients conditioned with high-dose etoposide (60 mg/kg intravenously for hematologic malignancy) [78]. Distal symmetrical sensory symptoms began within 2 months of the transplantation and improved slowly over months. One patient had a superimposed autonomic neuropathy and another had a peroneal neuropathy. A self-limited sensory neuropathy from etoposide conditioning also occurs in allogeneic transplant recipients. The delay in sensory symptoms for 1–2 months after etoposide is similar to the post-treatment worsening of neuropathy often seen with cisplatin and vincristine.

In high dose paclitaxel protocols for solid tumors, virtually all autologous transplant patients develop peripheral neuropathy, usually within 5 days of paclitaxel treatment [79]. Although reported as purely sensory in most affected patients, the neuropathy was sufficiently severe to require a walker in some patients.

Clinical features of cisplatin neuropathy are usually characteristic with large sensory fiber involvement, giving a proprioceptive deficit usually with preserved tactile and pin sensation and without muscle weakness [80]. By contrast, etoposide and paclitaxel neuropathies involve all sensory modalities [78,81]. Cisplatin neuropathy tends to correlate with cumulative dose rather than dose intensity. Symptoms usually occur after a cumulative dose of 300–600 mg/m^2. Also dose dependent is cisplatin ototoxicity, affecting high-frequency hearing initially and – with continued cisplatin courses – speech-frequency hearing loss, but very seldom producing vestibular toxicity [82]. In terms of cisplatin CNS toxicity, transient Lhermitte phenomenon occurs occasionally from an effect on the dorsal column of the cervical region of the spinal cord [83], and there are rare reports of cortical blindness and seizures [84].

Complications from supportive care drugs

Experienced transplant physicians tend to minimize the use of symptomatic medications early in the transplant course to avoid drug interactions, influence on the developing marrow, and untoward side effects. Extrapyramidal toxicity from antipsychotics, some antiemetic agents, and metoclopramide can interfere with rehabilitation progress after transplant.

Depression of the sensorium occurs very frequently in the first week after HCT from sedative–hypnotic drugs or analgesics. What can be especially misleading in lethargic or obtunded patients is unilateral pupillary dilatation from a scopolamine patch [85] used for drug-associated nausea. Similarly, ipratropium inhalation therapy given by mask has caused unilateral pupillary dilatation in transplant patients by inadvertent contact with the eye [86]. In these patients, pilocarpine 1% eye drops fail to produce miosis, confirming pharmacologic-induced mydriasis rather than pressure on the third cranial nerve from early transtentorial herniation. Recognition of this anticholinergic effect of scopolamine or ipratropium may prevent a needless head scan to exclude a cerebral mass lesion.

Many of the antibiotics used after transplantation have been associated with neurologic toxicity, for example, seizures from penicillin, piperacillin, metronidazole, and imipenem, encephalopathy from penicillin and metronidazole, hearing loss from aminoglycosides and vancomycin, peripheral neuropathy from metronidazole, and a myasthenia-like syndrome from aminoglycosides [87–90]. Since toxicity is often enhanced by renal insufficiency, special caution applies to those patients on calcineurin inhibitors and at risk for nephrotoxicity.

Acyclovir at high dose can cause tremor, agitation, or lethargy, occasionally with electroencephalogram epileptiform features [91]. In the setting of renal failure, reversible stupor and coma and occasionally generalized seizures have followed both oral and intravenous administration of acyclovir [92]. Delirium, which improved with dose reduction, was seen with ganciclovir treatment given at 10 mg/kg/day for CMV infection in a transplant patient [93]. Foscarnet most often causes renal and electrolyte disturbances, and low calcium and magnesium levels from foscarnet have been associated with paresthesias, muscle cramps, and rarely seizures [94].

Pre-transplantation neurologic screening

Pre-transplantation neurologic screening may identify patients particularly prone for neurologic complications, and in some cases this screening may lead to changes in treatment to minimize these complications. For example, anticonvulsant prophylaxis should be considered in transplant recipients with past seizures or a strong family history of epilepsy when these patients are treated with calcineurin inhibitors or other drugs known to lower the seizure threshold. Because of the cumulative toxicity of radiation therapy on the nervous system, it may be prudent to use preparatory regimens without fractionated total body irradiation in brain-damaged patients or in patients with degenerative CNS diseases. Because of the potential of producing disabling neuropathy, it is best to avoid high-dose etoposide or other peripheral nerve toxic conditioning agents in patients with severe diabetic neuropathy, hereditary neuropathies such as Charcot Marie Tooth, or significant pre-existing chemotherapy-associated neuropathies. Finally, it is prudent to screen donors carefully to avoid transfer of neurologic immune-mediated diseases such as multiple sclerosis.

CHAPTER 106

Vaccination of Allogeneic and Autologous Hematopoietic Cell Recipients

Trudy N. Small

Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Introduction

Yearly, over 30,000 autologous and 20,000 allogeneic hematopoietic cell transplants (HCT) are performed worldwide (reviewed in [1]), resulting in increasing numbers of survivors returning to the community and traveling abroad. Following HCT, all patients are immunodeficient, the extent and duration of which are dependent primarily on patient age, stem-cell source, presence or absence of graft-versus-host disease (GVHD), the intensity of immunosuppression needed to control GVHD, and/or receipt of B-cell-depleting monoclonal antibodies, such as rituximab (reviewed in [2,3]). Unless reimmunized, all studies show that pre-transplant seroprotection wanes with time and any transferred donor immunity is temporary (reviewed in [2,4]). Infections due to pneumococcus [5], influenza [6] varicella zoster virus (VZV) [7,8], and *Bordetella pertussis* [9] can cause serious illness even in immunocompetent individuals, particularly the young and the elderly [10]. Many of these infections occur more frequently in HCT recipients, remaining a significant cause of morbidity, rehospitalization, and mortality after successful transplantation (reviewed in [2,11]).

Scope of the problem

Multiple studies have demonstrated the increased risk of invasive pneumococcal disease following allogeneic and autologous HCT (reviewed in [2,11]). A prospective study in adults over 18 years of age by Kumar et al. demonstrated a 30.2-fold increase in the incidence of invasive pneumococcal disease (IPD) in HCT recipients compared with the general adult population [12]. The yearly incidence of IPD was 11.5/100,000 non-transplanted adults, compared with 590/100,000 and 199/100,000 allogeneic and autologous HCT recipients, respectively. Mortality in this study was 12.2%, similar to that observed in a study by Youssef et al. in which 6/47 patients with IPD following HCT died [13]. Shingles and post-herpetic neuralgia (PHN) also occur more frequently in HCT recipients than in age-matched controls (reviewed in [2,11]). The yearly incidence of herpes zoster in healthy individuals ranges from 1.2 to 3.4 cases per 1000 persons, increasing to 3.9–11.8/1000 persons over 65 years of age [7]. In a 2009 report from Japan [14], the cumulative incidence of VZV infection at 2 years following an autologous or allogeneic HCT was 22 and 34%, respectively; 35% of patients who developed herpes zoster developed PHN. In a prospective study by Ljungman et al., analyzing the impact of the 2009 pandemic H1N1 virus in 288 recipients of an allogeneic ($n = 222$) or autologous ($n = 66$) HCT, age and lymphopenia ($<0.3 \times 10^9$/L) were risk factors for pneumonia, need for mechanical ventilation, and death. In allogeneic HCT recipients, transplantation from an unrelated donor or human leukocyte antigen (HLA)-mismatched donor was a risk factor for lower respiratory tract disease, presumably due to the delayed immune reconstitution observed in this patient population compared with HLA-matched sibling HCT recipients [15].

Although each of the above infections is a potentially vaccine-preventable disease, not all patients are vaccinated after HCT [16–18] and, if vaccinated, not all patients respond equally (reviewed in [2,4,11]). Infections such as those due to VZV often occur early after HCT, posing safety concerns regarding administration of a live preventative vaccine. A 2010 survey by the Pediatric Blood and Marrow Transplant Consortium found that compliance with the 2000 Centers for Disease Control and Prevention (CDC) guidelines for individual vaccines ranged from 22 to 93%, with <20% of centers consistently vaccinating patients according to the guidelines [17]. In the study by Kumar et al., only 21% of patients who developed IPD were vaccinated against pneumococcus post-HCT [12]; 100% of the pneumococcal serotypes isolated from these patients would have been covered by the 23-valent polysaccharide pneumococcal and 92% by the 13-valent protein conjugate vaccine (PCV13). Although the live attenuated shingles vaccine is approved for immunocompetent individuals over 50 years of age [7], the safety of this vaccine in HCT recipients is largely unknown, and therefore it remains contraindicated in current guidelines until adequately studied [4]. The influenza vaccine, although well studied, is unfortunately least effective in patients at highest risk for severe complications, namely patients early after HCT, those requiring intensive immunosuppression for the treatment of GHVD, and recipients of rituximab [19–21].

The 2009 influenza pandemic [22], the continued increase in pertussis [23], the rising incidence of pneumococcal disease due to antibiotic-resistant strains [24], and outbreaks of measles [25] and mumps [26] in immunocompetent individuals highlight the need for effective revaccination of HCT recipients. This chapter reviews vaccine guidelines published since 2009, the studies on which these guidelines were based, and the immunogenicity of vaccines in this patient population, and discusses areas in which additional data are needed.

Loss of humoral immunity and vaccination guidelines

Unless revaccinated, the majority of patients will be susceptible to pertussis early after HCT (reviewed in [2,4,11,15]) and will have negative pneumococcal [27], *Haemophilus influenzae* [28], and tetanus [15] titers by 0.5–1, 1, and 1–2 years, respectively. Approximately 50% of patients will have titers against polio [28] and measles, mumps, rubella (MMR) [29] for at least 2 years after HCT, but almost all will become seronegative within 3–5 years [28,29]. The only patients who remain protected against measles for an extended period of time after HCT are those with a history of wild-type measles infection [29].

Following an autologous HCT, the time to lose immunity to vaccine-preventable diseases varies according to diagnosis, patient age, receipt of anti-CD20 monoclonal antibodies, and degree of immunity present prior to stem-cell harvest [4,30–33]. Whereas Horwitz et al. [30] showed that only 55% of patients with B-cell non-Hodgkin lymphoma (NHL) who received rituximab before and after an autologous HCT had protective tetanus titers 12–15 months post-HCT, Nørdoy et al. [32] found durable tetanus immunity in all rituximab-naïve patients evaluated 4–10 years after autologous HCT. Of 110 adult survivors of an autologous peripheral blood stem cell (PBSC) transplant performed primarily for Hodgkin lymphoma (HL) (*n* = 59) or NHL (*n* = 58), Small et al. found that at a median of 25.2 months after HCT, 90, 58, 40, 23, and 16% of patients lacked protective titers against pneumococcus, *H. influenzae*, measles, tetanus, and polio, respectively [34].

The European Group for Blood and Marrow Transplantation (EBMT) in 1995 [16] and 2005 [35] and the CDC in 2000 [36] developed standardized guidelines for the immunization of patients following HCT. These guidelines incorporated use of tetanus, diphtheria, polio, *H. influenzae*, pneumococcus, influenza, measles, mumps, and rubella vaccines. The EBMT and CDC guidelines, summarized in Table 106.1, differed in the number of doses of tetanus, polio, and *H. influenzae* recommended (two versus three) and PPV23 (one versus two) and the time to initiate revaccination (6 versus 12 months). In 2009, an international committee of infectious disease and transplant physicians met under the auspices of the Center for International Blood and Marrow Transplant Research (CIBMTR) to create an updated, unified international set of vaccine guidelines [4]. These guidelines were approved by the National Marrow Donor Program, the European Blood and Marrow Transplant Group, the American Society of Blood and Marrow Transplantation, the Canadian Blood and Marrow Transplant Group, the Infectious Diseases Society of America, the Society for Healthcare Epidemiology of America, the Association of Medical Microbiology and Infectious Diseases Canada, and the Centers for Disease Control and Prevention. In 2011, guidelines from the International Consensus Conference on Clinical Practice in Chronic GHVD were published specifically to address vaccination in this patient population [37].

Table 106.1 Summary of vaccine guidelines

Vaccine	2000 CDC	2005 EBMT	2009 CIBMTR
DTaP/Td/Tdap	2 doses each	3 doses each	3 doses each
IPV	12, 14 months	6–12 months	DTap <7 years, Tdap >7 years
HIB			6–12 months
Pneumococcus	PPV23	PPV23	13-valent
	12, 24 months	12 months	3 doses
			3–6 months
rHBV	Optional	Recommended	Country policy
MMR	24 months	24 months	24 months
Live attenuated varicella vaccine	No	Select patients	Select patients

The primary difference between the 2009 CIBMTR guidelines and those previously published was the recommendation to administer a series of three pneumococcal conjugate vaccines to all pediatric and adult transplant patients rather than primary immunization with one or two doses of the less immunogenic PPV23 [4]. In 2010, the guidelines were updated to include the newly licensed PCV13 vaccine, despite a lack of immunogenicity data in HCT recipients, owing to its broader coverage and the lack of availability of PCV7 [38]. PCV13 contains the same antigens included in PCV7 (4, 6B, 9V, 14, 18C, 19F, 23F) combined with antigens derived from serotypes 1, 3, 5, 6A, 7F, and 19A. The updated 2010 CIBMTR guidelines (Table 106.1) recommend (1) inclusion of three doses of PCV13 starting at 3–6 months post-HCT, (2) administration of PPV23 6–12 months following the third PCV13 in patients without chronic GVHD and consideration of a fourth dose of PCV13 in patients with chronic GVHD, (3) administration of the live varicella vaccine in select patient groups starting ≥24 months after HCT, and (4) the optional use of vaccines licensed since 2005 including the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) [9], the recombinant human papilloma vaccine [39], and the protein-conjugated meningococcal vaccine [40].

The 2011 guidelines from the International Consensus Conference on Clinical Practice in Chronic GVHD [37] advocate immunization starting at 6 months after HCT. The guidelines recommend a potential delay of only 3 months in patients on >0.5 mg/kg prednisone or receiving an intensive three-drug regimen to treat GVHD [37]. The guidelines call for three doses of the combination vaccine DTaP-HIB-inactivated polio vaccine (IPV), PCV, hepatitis B vaccine (HBV) in children at 6, 7, and 8 months after HCT followed by a booster dose of each vaccine at 18 months after HCT. Immunization against meningococcus, hepatitis A, and the human papilloma virus are optional. MMR and the live varicella vaccine may be given at ≥24 months after HCT provided that the patient is "immunocompetent." The inactivated influenza vaccine is advised in all patients who are at least 4–6 months after HCT at the start of the influenza season.

The immunogenicity of vaccines administered according to almost all vaccine guidelines remains unknown as most of the vaccine literature has not assessed patients immunized according to published guidelines. An exception is the study by Patel et al., who vaccinated 38 pediatric transplant recipients following an autologous (n = 10), HLA-matched related (*n* = 80) or unrelated (*n* = 200) HCT according to the recommendation of the 2002 Royal College of Paediatrics and Child Health [41]. These guidelines recommend immunization of autologous and HLA-matched transplant recipients starting at 12 months after HCT and unrelated HCT recipients starting at 18 months, due to concerns about delayed immune reconstitution in the latter group. Patients received 3-monthly doses of DTaP, IPV, HIB, and PCV7. Using this schedule, >90% of children responded to polio, tetanus, *H. influenzae* type B (HIB), and measles. Over 80% of patients responded to all seven serotypes included in PCV7 (threshold for response >0.35 μg/mL). Although this study did not correlate in vitro immunologic parameters and vaccine response, the proportion of responders was higher than that observed in most pediatric studies, other than reports in which patients were immunized following acquisition of preset immune milestones, such as CD4 cell count >200 cells/μL [42,43].

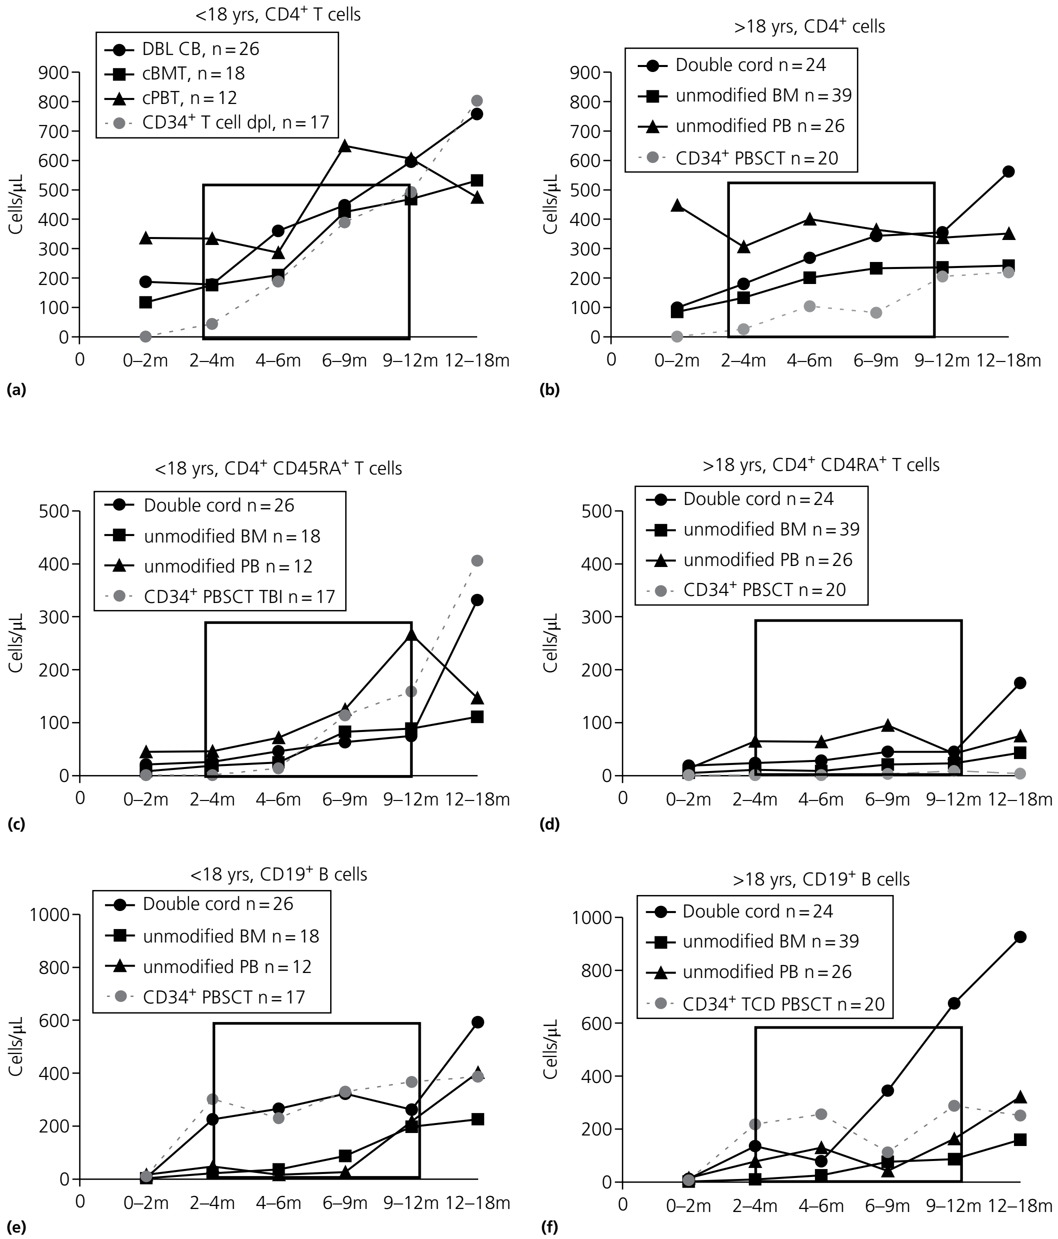

Figure 106.1 Comparison of CD4, $CD4^+$ CD45RA, and CD19 cells in patients <18 years (left) or >18 years (right) of age following double-cord, T-replete BM/PBSCT or $CD34^+$ T-cell-depleted unrelated PBSCT. Rectangle emphasize the differences in patient groups at 4–12 months after HCT, intervals during which revaccination is recommended.

There remain limited data assessing whether vaccination of all patients at fixed times after HCT is effective in patient groups whose immune recovery differs from that of an HLA-matched sibling. Figure 106.1 demonstrates the kinetics of recovery of median numbers of $CD4^+$ T cells (a, b), $CD4^+CD45RA^+$ T cells (1b, c), and $CD19^+$ cells (c, d) in patients younger or older than 18 years of age following an unrelated unmodified bone marrow or PBSC, double cord blood, or $CD34^+$ T-cell-depleted (TCD) HCT. At 3–12 months after HCT, a time when many guidelines recommend initiation of vaccines, there are clear differences in the median levels of populations required for T-cell-dependent B-cell responses. A significant number of patients will likely have absent or limiting populations of helper T cells and B cells required for vaccine response. Although vaccination based on fixed times after HCT may be sufficient for highly immunogenic vaccines, such as tetanus, polio, and the *H. influenzae* conjugate vaccine (reviewed in [12,13]), some studies suggest that response to recombinant hepatitis B vaccine (rHBV) and the pneumococcal conjugate vaccines require critical levels of T- and B-cell subsets [42–44]. For example, response to pneumococcal conjugate [43,44] and influenza vaccines [45] has been correlated with higher levels of naïve $CD4^+CD45RA^+$ and activated $CD4^+CD154^+$ T cells, respectively. Impaired B-cell responses are related to deficits in $CD27^+$ memory B cells capable of isotype switching. This subset can take years to recover after HCT [46,47], particularly in patients with chronic GVHD [48] and recipients of rituximab [3]. Roll et al. showed a significant correlation between levels of naïve $CD27^-$ B cells and response to the H1N1 vaccine [20]. Following PCV13, one study showed impaired response in patients lacking memory CD27$^+$ B cells capable of isotype switching [44].

Immunogenicity of vaccines after HCT

Current vaccine guidelines recommend three doses of tetanus/diphtheria toxoid, IPV, and the protein-conjugated *H. influenzae* and pneumococcal vaccines due to multiple studies demonstrating a higher proportion of responders following three doses of each vaccine compared with one or two doses (reviewed in [4]). Although patients who receive transplants from donors immunized against tetanus, diphtheria, and *H. influenzae* prior to stem-cell harvest develop protective antibody titers earlier after HCT than patients whose donors were not immunized prior to bone marrow (BM) harvest [49,50], this approach is only feasible in recipients of a related HCT. Donor immunization with PCV7, but not PPV23, has been shown to enhance recipient response to PPV23 after HCT [51].

Following three doses of tetanus, diphtheria, polio, and/or HIB, at least 50% of patients will seroconvert or mount a 3–4-fold rise in titer depending on when immunization is started (reviewed in [2,4]). Differences in the proportion of responders in published papers generally reflects differences in the age of the immunized patients, the proportion of patients requiring treatment for moderate to severe GVHD, the vaccine schedule utilized, and the threshold for response. For example, in a study by Parkkali et al. [52], over 95% of HLA-matched sibling bone marrow transplant (BM)T recipients immunized with IPV at 3, 6, and 12 months responded to all three polio serotypes (seroconversion or >4-fold response) compared with only a 50% response in the study by Ljungman et al. in 29 HLA-matched sibling bone marrow transplant recipients immunized at 12, 13, and 14 months [53]. In a study by Jaffe et al., 96% of 219 patients following an HLA-matched related ($n = 162$), HLA-mismatched ($n = 24$), or unrelated ($n = 69$) HCT developed a threefold or greater rise in titer against all three polio serotypes after receipt of three IPV vaccinations given at 2-month intervals [42]. Younger age at transplantation ($p = 0.01$) was the only factor associated with improved response to IPV vaccination [42].

Pertussis

In the last decade, pertussis has risen steadily in adolescents and adults, with an estimated incidence of 800,000 to 3.3 million cases/year (reviewed in [9]). In an effort to decrease the growing number of individuals with this disease, in 2005 two vaccines containing acellular pertussis were licensed for use in adolescents and adults for the first time in the United States [9]. The two vaccines (Tdap) contain similar amounts of tetanus and diphtheria toxoid, but differ in the amount of pertussis toxoid (PT). Adacel (Sanofi Pasteur, Toronto, Canada) contains 2.5 μg/dose PT compared with 8 μg / dose in Boostrix (GlaxoSmithKline Biologicals, Rixensart, Belgium) [9]. In 2006, the Advisory Committee on Immunization Practices (ACIP) recommended that all adolescents (aged 11–18 years) and adults (aged 19–64 years) receive a single dose of Tdap to replace their scheduled Td booster [9].

Following a single vaccine, autologous and allogeneic HCT recipients respond poorly to PT, despite an adequate response to tetanus and diphtheria toxoid. Of 41 adults and children immunized with one vaccine, only seven of 41 patients responded to PT, six of whom were <18 years of age when immunized [54]. Following an autologous HCT, two of 28 adult patient responded to a single Tdap [55]. This limited pertussis response is likely due to the small amount of PT contained in either vaccine [2.5 vs. 8 μg/dose) compared with 25 μg /dose in DTap, the vaccine used for primary immunization of infants and children under 7 years of age [9]. In view of this poor response, the 2009 CIBMTR guidelines recommend three doses of the 8 μg/dose Tdap in all HCT recipients, other than latex-allergic patients, who should receive Adacel [4]. To date, 99 patients, median age 49 years, have received three immunizations with Tdap containing 8 μg PT/dose at the Memorial Sloan-Kettering Cancer Center. Stem cells were derived from an HLA-matched related ($n = 36$) or alternative ($n = 63$) donor. There were no significant site or other adverse reactions. Overall response was 56%, including 11 of 13 patients <21 years and 46 of 89 patients >21 years of age ($p = 0.02$). In view of the morbidity and mortality of pertussis [18], recent data from California suggesting that vaccine efficacy decreases even in healthy children following the fifth dose of DTaP [56], and approval of Tdap in all individuals aged 7 years or older [57,58], it seems prudent to administer three doses of an age-appropriate pertussis vaccine, followed by a booster 6–12 months later to all HCT recipients, and to consider measuring pre- and post-vaccine titers to document response, particularly in adults caring for infants or patients with infant siblings.

Haemophilus influenzae and pneumococcal vaccines

Multiple studies have shown the poor response of HCT recipients to T-cell-independent B-cell antigens (reviewed in [2,4,11]). The polysaccharide pneumococcal vaccine PPV23 is poorly immunogenic in HCT recipients, particularly when given <1 year after HCT or at any time to patients with chronic GVHD (reviewed in [2,4,11,59,60]). Prospective studies demonstrating responses of 60–74% in patients given three doses of PCV7 following an autologous [61] or allogeneic HCT [51,63] are the basis for their recommended use in the 2009 CIBMTR guidelines [4]. These guidelines were the first to recommend a pneumococcal conjugate vaccine for any adult population. In 2011, the US Food and Drug Administration (FDA) approved a single dose of PCV13 for the prevention of pneumonia and IPD in adults over 50 years of age [64]. In 2012, a single dose of PCV13 was approved for patients over 19 years of age with an immunocompromising condition [65]. Whether a single dose of this vaccine will provide durable immunity in the latter populations needs to be evaluated. Three doses of PCV13 and consideration of a fourth dose in patients with chronic GVHD are currently recommended following HCT [4].

The best response to PCV7 (74%) was noted in a study by Meisel et al., which evaluated patients under 16 years of age [62]. It should be noted that in this study all patients were immunized at 6–9 months after HCT. Patients on immunosuppressive therapy (IST) at the time of immunization had a poorer response than those in whom IST was no longer required (42.9% vs. 80.6%, $p = 0.06$) [63]. In a retrospective study by Pao et al. [43], response was also superior in children compared with adults (88% vs. 45%, $p < 0.001$), although these children were not on IST. Although the PCV7 response in this study was adversely affected by older age ($p < 0.001$), individuals over 50 years old responded significantly better if vaccinated following acquisition of a circulating CD4 cell count ≥200 cells/μL and a PHA T-cell proliferative response of >75% lower limit of normal (11 of 19 vs. 0 of 8, $p < 0.006$). A similar trend was observed in patients with limited chronic GVHD. In all patients, higher levels of circulating CD4$^+$CD45RA$^+$ cells correlated with improved PCV7 response [43]. Meerveld-Eggink et al. [66] assessed PCV7 response in 26 patients (median age 56.5 years, range 44–67 years) following reduced-intensity conditioning. Patients were eligible for immunization if they were >12 months post-HCT and off IST. Owing to persistent GVHD, only 35% met the vaccination criteria at 12 months. The median time to first vaccination was 15 months, range 12–36 months. Following two doses of PCV7 administered 6 weeks apart, 73 and 62% of patients achieved a titer of 0.35 μg/mL or >1 μg/mL, respectively.

The current CIBMTR guidelines recommend three doses of PCV13 starting at 3–6 months after HCT. This is based on results of a multicenter randomized, prospective trial by Cordonnier et al. testing non-inferiority of PCV7 response initiated early (3 months) or late (9 months) after HCT [67]. Patients aged 5–65 years were randomized to three monthly doses of PCV7 starting at 3 ($n = 75$) or 9 ($n = 83$) months after HCT, followed 8 months later by PPV23. All patients received myeloablative conditioning and most received an HLA-matched related transplant. Grade II–III GVHD was seen in 22 and 18% of patients randomized to early or late vaccination, respectively. No GVHD, limited GVHD, or extensive chronic GVHD was seen in 57, 35, and 8% of patients vaccinated early and in and 55, 31, and 13% of patients immunized later. When a threshold titer >0.15 μg/mL against all seven vaccine strains measured 1 month after the third PCV7 (primary end-point) was utilized, the percentage of responders was similar in both groups (79% vs. 82%, $p = 0.64$). Ad hoc analysis using a threshold of 0.5 μg/mL resulted in a similar but lower proportion of responders in the early and late vaccine groups (56% vs. 54%, $p = 0.84$). The percentage of patients who retained a titer of >0.15 μg/mL against all seven serotypes 24 months after HCT was significantly lower in patients who started vaccination at 3 months compared with 9 months after HCT (59% vs. 83%, $p = 0.013$]. At 24 months after vaccination, 34% vs. 55% of patients retained a titer of >0.5 μg/mL ($p = 0.54$). Factors associated with poor response were presence of chronic GVHD and older donor age. One month following immunization with PPV23, 80% vs. 87% of patients responded to PPV23 specific serotypes 1 and 5 (threshold response: 0.15 μg/mL) compared with 42% vs. 60% when a threshold response of 0.5 μg/mL was considered positive ($p = 0.08$) [68]. In a subset of patients ($n = 28$), functional antibody measured by an opsonophagocytic assay was compared with immunoglobulin G (IgG) levels measured by enzyme-linked immunosorbent assay (ELISA). The study showed a significant correlation between the two assays, demonstrating that the conjugate vaccine induced functional antibody [69].

Until results of the recently completed multicenter international trial of PCV3 followed by PPV23 in allogeneic HCT recipients is published, there are limited data on the immunogenicity of this vaccine following HCT. A report of 59 patients (median age 39 years) who received three doses of PCV13 administered 1–3 months apart was presented at the American Society of Hematology Annual Meeting in December 2011 [44]. Patients in this study were immunized upon acquisition of minimal milestones of immune competence (CD4 cell count >200 cells/μL and IgG level >500 mg/dL at least 6 weeks off γ-globulin replacement therapy). The median time to vaccination was 452 days (range 143–1187 days) after HCT. Time to vaccination was significantly shorter in patients <21 versus >21 years of age (median 318 vs. 498 days, $p = 0.006$) and significantly longer in patients who received rituximab after HCT (median 610 vs. 405 days, $p = <0.001$). Response was defined as seroconversion (>1 μg/mL) or a threefold rise in titer against serotypes 1, 3, 4, 14, 19, 23, 26, 51, and 56. The overall response was 73%. The response was 87% in patients younger than 21 years compared with 67% in older patients. Poorer responses were observed in recipients of rituximab after HCT despite a median CD19 cell count of 342/μL at the time of vaccination. Response following PCV13 correlated with higher levels of circulating $CD4^{+}CD45RA^{+}$ T cells/ul ($p = 0.03$) and $CD27^{+}$, IgM^{-} (memory isotype switched) B cells/μL ($p = 0.03$). In this limited sample, PCV13 was found to be very immunogenic when given upon acquisition of preset immune milestones. The results of the international PCV13 trial will determine whether immunization at earlier times after HCT will yield similar results.

Meningococcus

Despite rapid and appropriate treatment for meningococcal disease, 10–14% of infected patients die and up to 20% of survivors experience significant morbidity, including vasculitis, suppurative arthritis, myocarditis, and deafness [70]. In 2005 [71], the first protein-conjugated tetravalent meningococcal vaccine was licensed in the United States, followed by a second vaccine in 2010 [72]. Both vaccines contain antigens derived from meningococcal serogroups A, C, Y, and W-135. Parkkali et al. demonstrated that although allogeneic HCT recipients including those with GVHD are capable of responding to the meningococcal polysaccharide vaccine, a rapid decrease in antibody titers was observed 6 months after vaccination [73]. Of 46 pediatric patients immunized with the tetravalent meningococcal conjugate vaccine following an HLA-matched sibling ($n = 17$) or an alternative donor ($n = 29$), only 15% responded to all four serogroups and 35% responded to none [74]. Although receipt of a T-cell-depleted graft was associated with a poorer response ($p = 0.044$), response was not affected by patient age, diagnosis, time to vaccination, or prior history of GVHD [75]. Eight of 14 patients who did not respond to the first vaccine had a complete response to a second dose. These data suggest that the response to MCV4 is suboptimal in HCT recipients and that pre- and post-vaccine titers, particularly in patients entering college or traveling to endemic areas, should be assessed to ensure adequate protection. Administration of a two-dose series, as currently recommended for patients with asplenia, complement deficiency, and HIV infection, should be considered in this patient population [75].

Influenza

Influenza, particularly if acquired early after HCT, can be associated with significant morbidity and mortality (reviewed in [76]). Although immunization with the inactivated influenza vaccine has been shown by Machado et al. to decrease the risk of influenza when administered >6 months after HCT (two of 19 vaccinated compared with 12 of 24 unvaccinated) [77], the majority of serious infections occur earlier after HCT when vaccine response is poor (reviewed in [76]). Engelhard et al. showed that none of the 10 patients immunized <6 months after an autologous or T-cell-depleted allogeneic HCT developed protective hemagglutination inhibition (HI) titers (>1:40) compared with nine of 14 patients immunized >2 years after HCT [78]. Receipt of a second immunization 4 weeks later did not significantly increase the proportion of responders.

Several studies have evaluated the response of HCT recipients following immunization with the 2009 pandemic influenza A/H1N1 vaccine. Gouérin-El Khourouju et al. compared T- and B-cell responses between 14 vaccinated and 14 unvaccinated pediatric HCT recipients; 10 of 15 vaccinated patients received an HLA-matched sibling HCT. The median time to vaccination was 5.7 months after HCT. Immunized children had higher T-cell proliferative responses, higher antibody levels, and a predominance of

IL-2, rather than γ-interferon intracellular cytokine production [79]. Of 82 allogeneic HCT recipients immunized with the H1N1 vaccine at a median of 19 months after HCT [80], 51% had seroprotective titers (≥1:40 hemagglutination level) against the H1N1 antigens. Seroconversion could not be measured in this study owing to a lack of pre-vaccine titers. Chronic GHVD and type of conditioning did not affect whether titers ≥1:40 were detected after vaccination. Seroprotection was affected by the interval between immunization and HCT and prior rituximab treatment. Only one of 11 patients who received rituximab the year before vaccination had seroprotective levels following immunization [80]. Gueller et al. evaluated seroconversion in 14 patients immunized with an AS03-adjuvanted H1N1 vaccine at a median of 19.7 months (range 4.7–49.3 months) following an allogeneic ($n = 14$) or autologous ($n = 3$) HCT [81]. The rate of seroconversion was 41.2% after the first vaccine, and notably 81.8% in 11 patients who received a second dose. Engelhard et al. evaluated antibody response following an ASO3-adjuvanted A/California/7/2009 (H1N1) virus vaccine in 55 allogeneic and 23 autologous HCT recipients [82]. The median patient age was 50 years. The median time to immunization was 27 months (range 1–290 months). Approximately 50% of allogeneic transplant recipients received a reduced-intensity conditioning regimen. Prior to immunization, 17.9% had protective titers HI titers ≥1:40. Logistic regression analysis demonstrated that development of HI titers ≥1:40 was significantly associated with higher lymphocyte counts and higher baseline titers. Although responses were observed, patients at high risk of complications from influenza had the poorest response.

Owing to the variable response to the seasonal and pandemic influenza strains, current vaccine guidelines recommend yearly inactivated influenza vaccination in patients >6 months after HCT, strongly advocate immunization of household members and caretakers, and stress prompt evaluation of patients with respiratory symptoms to allow timely administration of anti-viral therapy in polymerase chain reaction (PCR)-positive patients [11].

Hepatitis B

Current ACIP guidelines recommend universal rHBV immunization for all individuals less than 18 years of age [83]. Proof of vaccination is often mandatory for school entry and certain jobs. Machado et al. [84] reported a 100% seroconversion rate in 50 HCT recipients immunized >1 year after transplant. Despite this initial response, 60% of patients became seronegative 1 year after immunization. Jaffe et al. evaluated the rate of seroconversion in 267 seronegative patients immunized with three doses of rHBV, vaccinated on the basis of preset immune milestones (circulating CD4 cell count ≥200 cells/μL, IgG level ≥500 mg/dL and PHA response≥75% of the lower limit of normal) [42]; 65% of patients received an HLA-matched related HCT, 9% an HLA-mismatched related HCT, and 25% an unrelated donor HCT. A total of 64% of patients seroconverted [58], including 73% of children and 59% of adults ($p = 0.02$). In multivariate analyses, seroconversion was adversely affected by age >18 years ($p < 0.01$) and prior chronic GVHD ($p < 0.000$), but not by receipt of a T-cell-depleted or alternative donor graft [42]. Serial titers were evaluated in 98 patients, 80 of whom remained immune for more than 5 years following immunization. The higher percentage of patients with sustained immunity in this study compared with the study of Machado et al. [84] suggests qualitative and/or quantitative differences in the circulating memory T and/or B cells present at the time of vaccination.

Hepatitis A

Current ACIP guidelines recommend universal routine immunization of all children 12–23 months against hepatitis A virus (HAV) (reviewed in [85]). Hepatitis A vaccination is also recommended for persons who are at increased risk for infection, such as healthcare workers, for persons who are at increased risk for complications from hepatitis A, and recently for household and close personal contacts of children adopted from countries with high or intermediate rates of hepatitis A [85]. Only three studies have evaluated the prevalence and persistence of hepatitis A titers before and after HCT, respectively, and there are no published reports on the immunogenicity of the HAV vaccination post-HCT. Dignani et al. evaluated HAV titers in 36 adult patients, 88% of whom received an autologous HCT. At a median follow-up of 12 months, 14% of seropositive patients became seronegative [86]. In 71 adult patients, median age 26 years, 91.6% of whom received an autologous HCT, loss of seroprotection was reported in 11.2% [87]. Unal Ince et al. studied HAV titers in 81 pediatric recipients of an allogeneic HCT performed in a single institution from 1997 to 2006 [88]. Of the 49 patients with documented hepatitis A serology prior to HCT, 23 were seropositive. Ten of 23 patients became seronegative at a median of 12 months after HCT (range 12–32 months). Loss of protective antibody was higher in recipients of grafts from HAV-seronegative donors (75% vs. 26%). Of the 39 HAV-seronegative patients immunized at the Memorial Sloan-Kettering Cancer Center, seroconversion was observed in 64% of patients given two vaccines, including 10 of 18 (55%) patients transplanted from an unrelated or HLA-mismatched donor (T.N. Small, unpublished data).

Measles, mumps, rubella, varicella zoster (VZ)

Despite recent outbreaks of mumps and measles [25,26], there are limited data on the immunogenicity and durability of response following immunization with MMR, particularly in recipients of a TCD or alternative donor HCT or any adult HCT population (reviewed in [89]). Most studies have been performed in children and young adults at least 24 months following an autologous or allogeneic HCT. The majority of vaccinated allogeneic transplant recipients had no evidence of GVHD and were not on IST. In these patient populations, at least 60% of patients seroconverted to measles and/or mumps (reviewed in [90]). During a large outbreak of measles in Brazil, Machado et al. evaluated the response of 51 patients following an autologous ($n = 10$) or allogeneic ($n = 41$) HCT vaccinated earlier post-HCT, i.e. at 9–18 months [90]. Approximately half of the patients in this study were actually on IST, the majority due to extensive chronic GVHD. Despite this, no patient had a serious adverse event. Seven of nine patients with negative titers (<100 IU/mL) seroconverted and the majority of patients with pre-existing titers mounted a threefold response.

Varicella/herpes zoster

To date, four studies have evaluated the live attenuated varicella vaccine (LAVV) following an allogeneic or autologous transplantation (reviewed in [89]). These studies include a total of 34 autologous and 96 allogeneic HCT recipients all under the age 20 years [89]. The vaccine was immunogenic in at least 50% of patients and appears to be safe when given according to preset levels of immune competence, generally defined as a circulating CD4 cell count of >200 cells/μL and response to at least one non-live vaccine administered after HCT. In the two largest series reported to date, response following the LAVV was 55 and 64%, respectively, with additional patients seroconverting following a second dose [91,92]. As two doses of the LAVV are currently recommended for healthy VZV-seronegative individuals, studies prospectively assessing the immunogenicity of a two-dose schedule in eligible HCT are needed [93].

The LAVV Zostavax [7] is currently approved for the prevention of herpes zoster in VZ-*seropositive immunocompetent* individuals over 50 years of age. This vaccine should not be confused with Varivax, the live vaccine approved to prevent primary varicella in VZ-*seronegative* individuals (reviewed in [89]). Zostavax contains approximately 14 times more plaque-forming units (reviewed in [7]) than Varivax, and is currently not approved in immunocompromised patients. Since 2007, the University of California at San Francisco has immunized primarily autologous HCT recipients with Zostavax, at the discretion of the treating physician, in patients felt to be immunocompetent and in whom the potential benefit was felt to outweigh potential risks [94]. Naidus et al. retrospectively assessed this experience in 31 patients following an autologous ($n = 26$), HLA-matched related ($n = 3$), or unrelated ($n = 2$) HCT [94]. The median patient age at vaccination was 55 years (range 31–80 years) and the median time from HCT to vaccination was 482 days in autologous HCT recipients and 1323 days in the five allogeneic HCT recipients. At a median follow-up of 268.5 days, only one patient had developed shingles, which was limited. This occurred in a patient with multiple myeloma following an autologous HCT [94]. There is a great need for a prospective study assessing this vaccine following autologous and allogeneic transplantation. A report of a 76-year-old woman receiving chemotherapy for recurrent breast cancer who developed disseminated varicella following Zostavax administration emphasizes the risk of this vaccine in patients whose immune system is compromised [95]. Until studied in the context of a trial, Zostavax is currently contraindicated in the 2009 CIBMTR vaccine guidelines [4]. Hata et al. evaluated the use of a heat-inactivated varicella zoster vaccine in patients following autologous HCT [96] in a randomized controlled trial which showed that 13% of patients who received the heat-inactivated vaccine developed herpes zoster within 12 months of HCT compared with 33% in the control group. Although inactivated vaccines to prevent herpes zoster are currently undergoing testing in HCT recipients, they are not commercially available.

Other live vaccines

Although additional live attenuated vaccines are licensed for use in immunocompetent individuals, most are contraindicated in HCT recipients. These vaccines include the live attenuated intranasal influenza vaccine, the live attenuated rotavirus vaccine, and the yellow fever vaccine (reviewed in [89]).

The live attenuated intranasal influenza vaccine has been evaluated in pediatric patients with asymptomatic or mildly symptomatic HIV infection and in oncology patients under 21 years of age (reviewed in [89,97]). Although the vaccine was well tolerated and did not result in prolonged viral shedding, antibody responses following this vaccine were inferior to those observed following the inactivated trivalent influenza vaccine and remain contraindicated given the availability of the inactivated alternative.

The live rotavirus vaccine is contraindicated post-HCT owing to a lack of safety information and documented cases of rotavirus infection following administration to infants with severe combined immunodeficiency have been published [11,98].

The yellow fever vaccine can cause life-threatening complications, even in healthy individuals [99]. There are, however, case reports of successful vaccination of HCT patients who were >2 years following HCT, off IST, without GVHD (reviewed in [89]). Nevertheless, owing to the limited safety data, this vaccine is currently contraindicated in all patients <24 months post-HCT and in those with chronic GVHD or on IST at any time post-HCT. For patients living in or traveling to endemic areas who do not have these risk factors, the risk–benefit ratio in individual patients is advised [4].

Administration of live vaccines and isolation of household contacts given live vaccines

Immunocompetent family members and household contacts of HCT recipients *should not* receive the oral polio virus, smallpox vaccine, or live influenza vaccine owing to concerns regarding transmission of vaccine virus to an immunocompromised host. The 2009 CIBMTR guidelines recommend that MMR be given to household contacts who are more than 12 months old and are not pregnant or immunocompromised as no evidence exists that live attenuated vaccine strain viruses in MMR vaccine are transmitted from person to person [11]. The guidelines also recommend that Varivax be given to susceptible, eligible household contacts owing to the greater risk and morbidity from acquisition of wild-type varicella from a VZ-seronegative family member or household contact compared with transmission and complications from the attenuated vaccine strain [11]. If a post-vaccination rash develops within 42 days of vaccination, the vaccinee should avoid contact with HCT recipients until the rash has totally crusted over.

Conclusion

All vaccine guidelines, including those published recently, acknowledge in their introduction the variable kinetics of immune reconstitution of patients undergoing transplantation today. Although

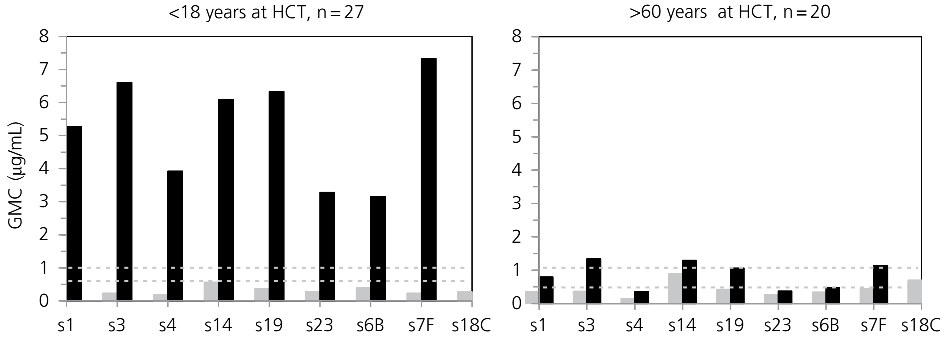

Figure 106.2 Geometric mean antibody concentration (GMC) in patients <18 or >50 years of age before (gray boxes) and after (black boxes) vaccination with three doses of PCV13.

immunization of patients using a standard timetable without documentation of pre- and post-vaccine titers is a less complicated and more cost-effective intervention, the protection afforded by this strategy may be suboptimal for patients who historically have responded poorly to vaccination, and ultimately more costly. Studies reported in this chapter have shown the effect of age on vaccine response, particularly following the pneumococcal conjugate vaccine, rHBV, measles, and mumps. The number of transplants performed in patients over the age of 60 years reported to the CIBMTR continues to increase [100]. Even immunocompetent individuals of this age respond poorly to many vaccines. Figure 106.2 demonstrates the difference in the magnitude of responses following three doses of PCV13 in 47 patients, 27 below the age of 18 years, compared with the response of 20 patients above the age of 60 years. Although responses were seen in both groups, the magnitude of response was different. The duration of seroprotection in these two populations will likely differ and studies addressing this are needed, as are prospective, multicenter trials testing current guidelines in groups who historically are poor responders, such as patients on IST, and those underrepresented in the vaccine literature, such as cord blood HCT recipients. The latter population may respond significantly differently than other populations owing to the complete lack of transfer of any donor memory cells. Ideally, future trials will include in vitro studies of immune reconstitution in order to identify surrogate markers of vaccine success or failure. In vitro correlates of vaccine responses might allow earlier revaccination of patients with the requisite T- and B-cell populations and prevent premature vaccination and/or risk in patients unable to respond. For patient groups with poor response, additional trials assessing vaccine adjuvants should be undertaken [101].

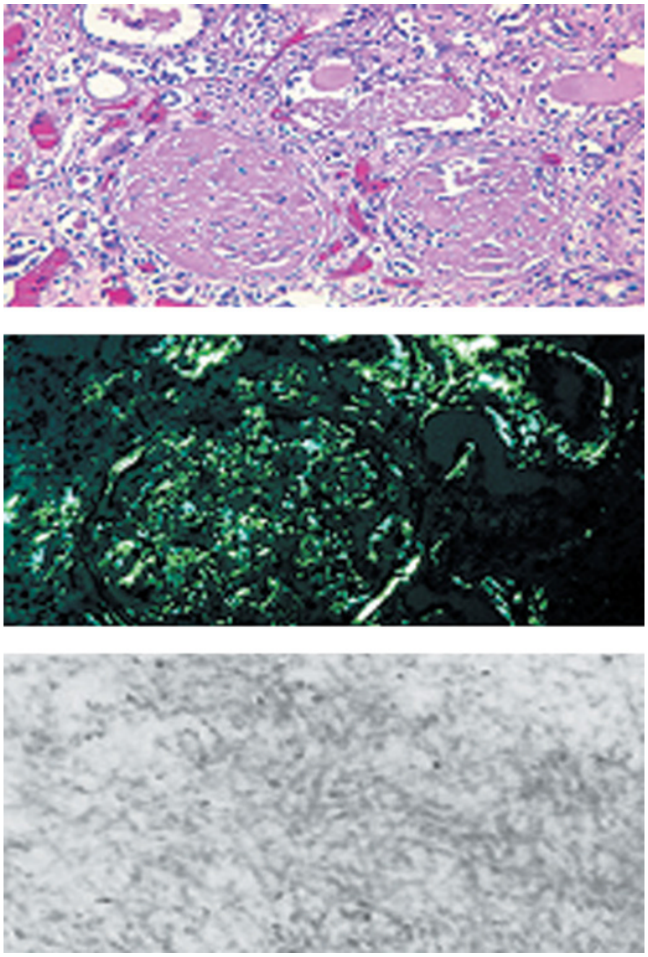

Figure 60.1 Renal biopsy showing amyloidosis. These images show three views of a renal biopsy: with periodic acid–Schiff (PAS) staining showing amorphous material in glomeruli (top), Congo Red staining showing apple-green birefringence in polarized light (middle), and electron microscopy showing non-branched linear fibrils about 10 nm in length.

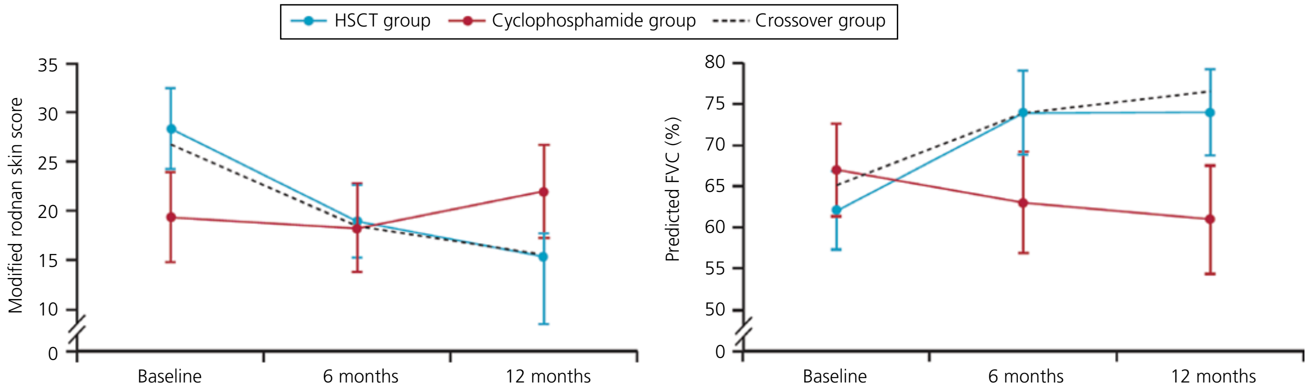

Figure 66.6 Improvement in skin score and lung function after HDIT and autologous HCT in comparison with conventional immunosuppressive therapy. All 10 patients randomly allocated to receive HSCT improved at or before 12 months' follow-up, compared with none of nine allocated to cyclophosphamide (odds ratio 110, 95% CI 14.04–∞; $p = 0.00001$). Eight of nine controls had disease progression (without interval improvement) compared with no patients treated by HSCT ($p = 0.001$), and seven patients switched to HSCT. Compared with baseline, data for 11 patients with follow-up to 2 years after HSCT suggested that improvements in mRSS ($p < 0.001$) and forced vital capacity ($p < 0.3$) persisted. Figure 68.1 GMP compliant approaches for the generation of CMV-specific T cells. (a) "Classic" ex vivo expansion method of CMV-CTL manufacture where antigen-presenting cells (APCs) are prepared using either dendritic cells or monocytes or EBV-transformed B lymphoblastoid cell lines (LCLs). The APCs are then either pulsed with CMV peptides or protein or infected with CMV lysate or transduced with an adenoviral vector expressing the CMV pp65 transgene. The APCs are then irradiated and used to stimulate peripheral blood mononuclear cells (PBMCs) from the same donor. Approximately 9–12 days later, and weekly thereafter, the T cells are restimulated with the APCs usually in the presence of IL-2. At the end of the CTL manufacturing process (approximately 4 weeks), the CTLs are frozen and released. Functional testing is performed prior to infusion into the patient. (b) This shows how CMV-specific T cells can be selected using multimer selection. In the example shown, T cells recognizing the HLA A2-restricted CMV pp65 epitope NLV are selected directly from the donor PBMCs by first incubating with the HLA–peptide tetramer and then selecting the tetramer-positive T cells with magnetic beads. This process generally takes less then 1 day of processing. (c) This shows an alternative method of rapidly generating a CMV-specific T cell line using the gamma capture technology. Donor PBMCs are stimulated with either recombinant CMV protein or CMV lysate or GMP grade-selected HLA-restricted CMV peptides or overlapping peptides spanning entire CMV antigens such as pp65. After overnight stimulation, IFN-γ-secreting cells are selected using a Cytokine Secretion System and a CliniMACS immunomagnetic separation device (both from Miltenyi Biotech) which "capture" the IFN-γ-secreting CMV-specific T cells. CMV-specific T cells selected using this methodology can either be infused immediately after the isolation procedure or cryopreserved for future use. The manufacturing time for this procedure is 1–2 days.

Figure 69.1 Cell culture approaches for adoptive transfer of lymphocyte subsets. Culture conditions required for distinct lymphocyte subsets vary, depending on the activation and costimulatory requirements. CTLs express αβ TCRs and are stimulated by APCs that express MHC class I. CTLs require 4-1BB stimulation for expansion, and have been expanded by the addition of feeder cells or artificial APCs (aAPCs) that express the costimulatory ligands. CD4 T cells are stimulated by APCs that express peptide-loaded MHC class II. The dominant costimulatory molecule for CD4 cells is CD28. Effector CD4 cells can be stimulated by beads or cell-based aAPCs in the presence of various cytokines. Regulatory CD4 T cells (Treg cells) require culture in IL-2, and the addition of number of reagents to the culture may enhance the suppressive functions of ex vivo expanded Treg cells.

Figure 69.2 T cells can be engineered to have retargeted specificity for tumors. (a) Endogenous T cells express a TCR with a single specificity. Bispecific T cells are created by the introduction of genes that encode proteins that recognize antigens expressed by target tumor cells. (b) These genes can encode natural TCRs that function in the same MHC-restricted manner as endogenous TCRs but have tumor-antigen specificity. (c) Alternatively, these genes can encode chimeric tumor antigen–specific receptors (CARs) that target surface antigens in an MHC-independent fashion. T bodies express an extracellular ligand generally derived from an antibody and intracellular signaling modules derived from T-cell signaling proteins.

Phagocytosis and destruction of C3b-coated bacteria

Figure 75.1 The acute inflammatory response. Neutrophils are among the first cells to arrive at the scene of an infection and are important contributors to the acute inflammatory response. As the neutrophil rolls along the blood-vessel wall, the L-selectin on its surface binds to carbohydrate structures such as sialyl-LewisX on the adhesion molecules on the vascular endothelium, and its progress is eventually halted. As the neutrophil becomes activated, it replaces L-selectin with other cell-surface adhesion molecules, such as integrins. These molecules bind E-selectin, which is present on the blood-vessel wall as a result of the influence of inflammatory mediators such as bacterial lipopolysaccharides and the cytokines interleukin-1 and TNFα. The activated neutrophil then enters the tissues, where it is attracted to the infection site by a number of chemoattractants. The neutrophil can then phagocytose and destroy the C3b-coated bacteria. Figure 76.4 Upper panel: G-banded karyotypes from an abnormal clone in the marrow of an FA patient. This is a hyperdiploid metaphase cell with 48 chromosomes including two extra derivative chromosomes (designated by arrows); one derivative chromosome is composed of two copies of the long arm of chromosome 1 and the other contains two copies of a small portion of the long arm of chromosome 3. This cell contains a total of four copies of portions of chromosomes 1 and 3. Lower panel: A karyotype of the same abnormal clone as above, as characterized by fluorescent in situ hybridization (FISH) using a multicolor paint probe (Vysis spectral vision M-FISH). M-FISH confirmed that the two derivative chromosomes detected by G-banding represented extra copies of portions of chromosomes 1 and 3. Source: Courtesy Betsey Hirsch PhD.

Figure 76.7 Model of the FA pathway in DNA repair compiling the most recent data. (a) Step 1: DNA damage and stalled replication fork signal ATR results in phosphorylation of the FANCA, E and G of the core complex, and FANC D2 and I of the I-D complex, RAD51C and histone H2AX as well as activation of p21 which downregulates USP1 deubiquitination enzyme and in turn permits ubiquitination of FANC D2 and I. Step 2: Upon recognition of the intrastrand DNA cross-link (ICL), FANCM and FAAP24 and FANCM-associated histone fold 1/2 bind near the site of the intrastrand cross-link and recruit the 8-member core complex which assembles the core nuclear ubiquitin ligase complex which monoubiquinates FANCD2 and FANCI. (b) Step 3: The modified I-D protein complex associates with chromatin and recruits FAN1 critical to excision of the ICL and formation of 3′ flaps of ssDNA for repair. Step 4: Downstream proteins FANCN, D1, J, O and P, and BRCA1 assemble and nucleate the single strand DNA with RAD51C. Step 5: This enables homologous recombination and ICL/double-strand break (DSB) repair. Mutations any of the FANC genes leads to inability to repair ICL efficiently. Loss of the FA pathway leads to chromosomal aberrations upon exposure to cross-linking agents such as diepoxybutane (DEB), leading to an infrequency of chromosomal breaks and radial figures as shown in the side panel. Source: Courtesy of Betsey Hirsch PhD. Model based on a compilation of data [29–52].

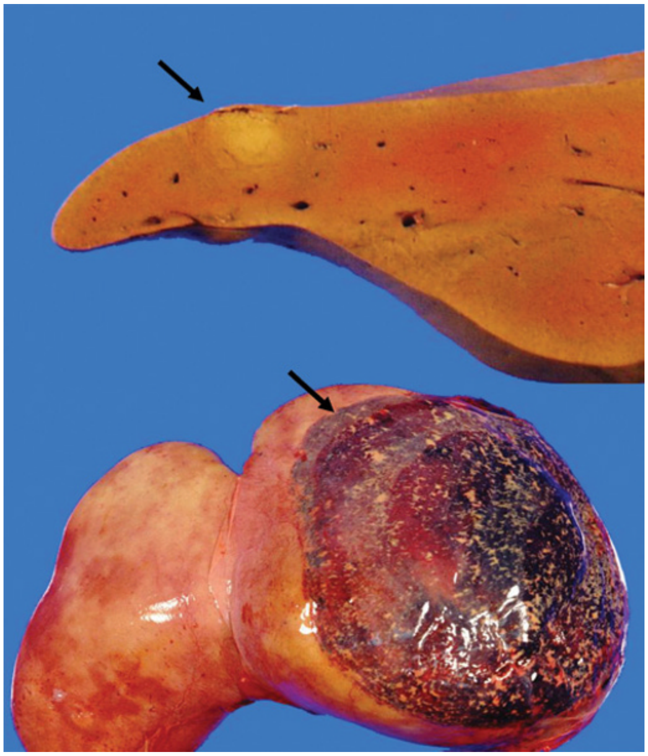

Figure 76.11 Hepatic adenoma. Pathological specimen obtained at autopsy from a patient with FA with multiple adenomata not revealed by ultrasound prior to HCT. Lower panel shows area of massive intrahepatic hemorrhage in one previously unidentified adenoma. Source: Kumar et al. 2004 [89]. Reproduced with permission of Lippincott Williams & Wilkins.

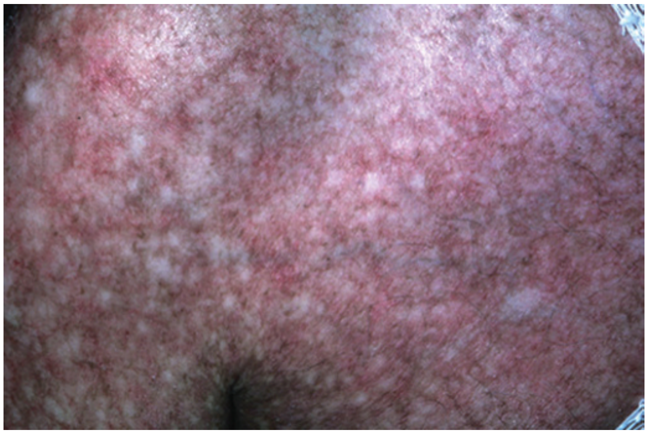

Figure 84.5 Poikiloderma, a diagnostic manifestation of cGVHD, which includes both atrophic and pigmentary changes. Note the combination of reticulated pattern, epidermal atrophy (cigarette-paper wrinkling of the skin surface), erythema, and brown pigment forming the borders of skincolored or depigmented skin.

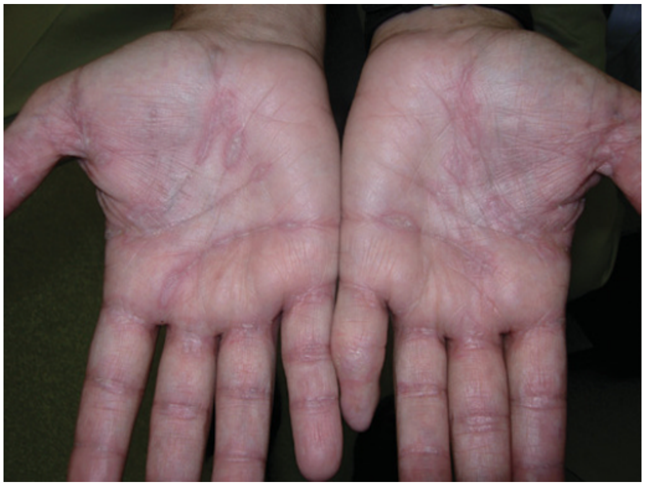

Figure 84.6 Lichen planus-like eruption involving the palmar surfaces, a diagnostic manifestation of cGVHD. Note the erythematous/violaceous flat-topped papules or plaques with or without surface reticulations or a silvery or shiny appearance on direct light.

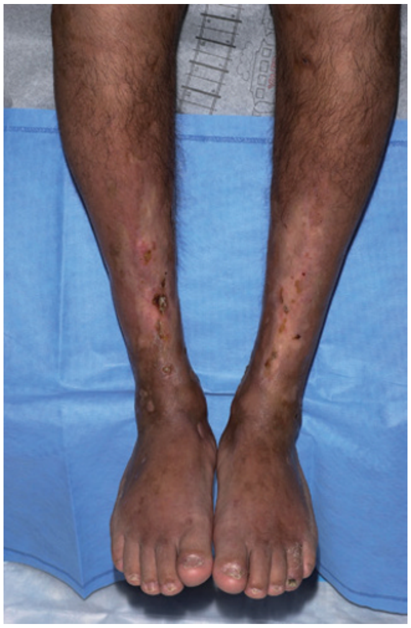

Figure 84.7 Diffuse deep sclerotic features involving the lower extremities, a diagnostic feature of cGVHD. Note the non-movable/hidebound subcutaneous tissues, erosions, and ulcerations, loss of hair follicles, and toenail dystrophy.

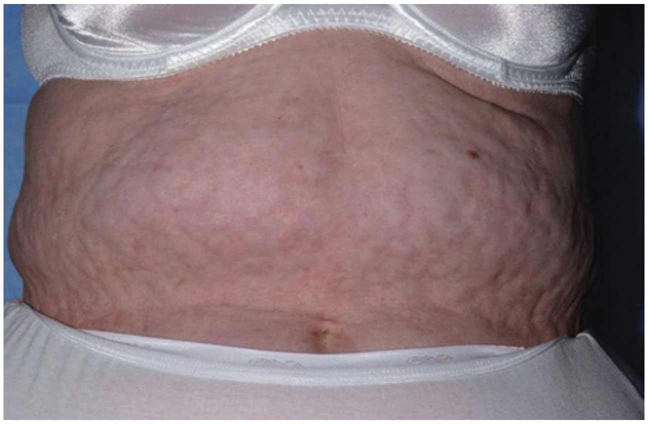

Figure 84.8 Alternative manifestation of deep sclerosis common in areas of excess subcutaneous tissue such as the abdomen, upper arms, and buttocks. Tissue is not hidebound but demonstrates prominent rippling, dimpling, or a cellulite-like appearance.

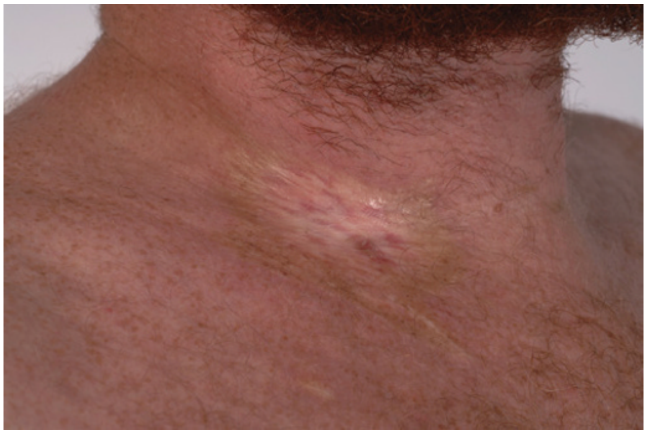

Figure 84.9 Morphea-like superficial sclerotic skin changes, a diagnostic feature of cGVHD. Note the localized, patchy areas of movable smooth or shiny skin with a leathery-like consistency, often with dyspigmentation. In this picture, there is a fibrotic, hypopigmented area in the center of the plaque with a slightly hyperpigmented border.

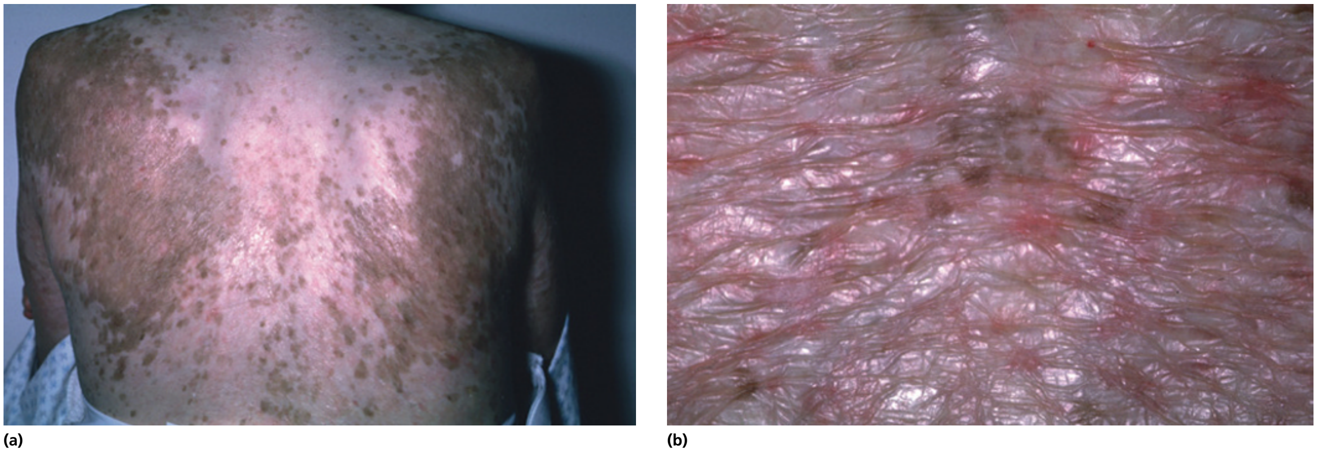

(a) (b)

Figure 84.10 Lichen sclerosis-like lesion, a diagnostic manifestation of cGVHD. Note the discrete to coalescent gray to white movable papules or plaques, with a shiny appearance and leathery consistency (a) or cigarette paper-like textural changes (b).

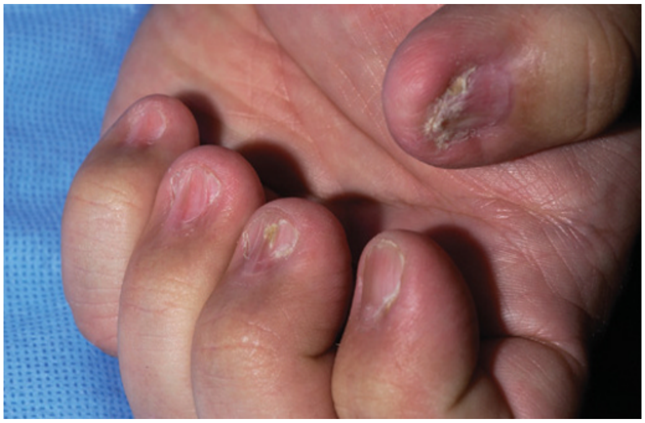

Figure 84.11 Nail dystrophy involving multiple digits is a distinctive feature of cGVHD, although it is insufficient alone to establish the diagnosis. Note the longitudinal ridging, splitting, and brittle nail features, and also periungual erythema.

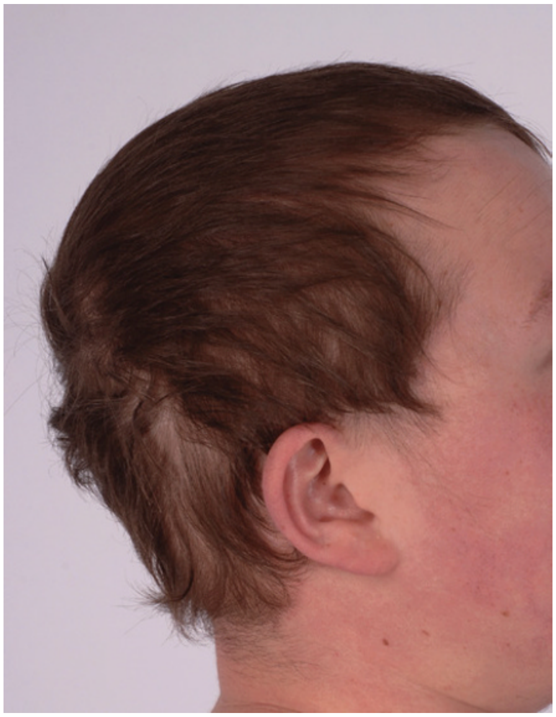

Figure 84.12 New onset of patchy alopecia after recovery from chemoradiotherapy is another distinctive manifestation of cGVHD (but is insufficient alone to establish the diagnosis). Patchy alopecia may involve loss of scalp or body hair.

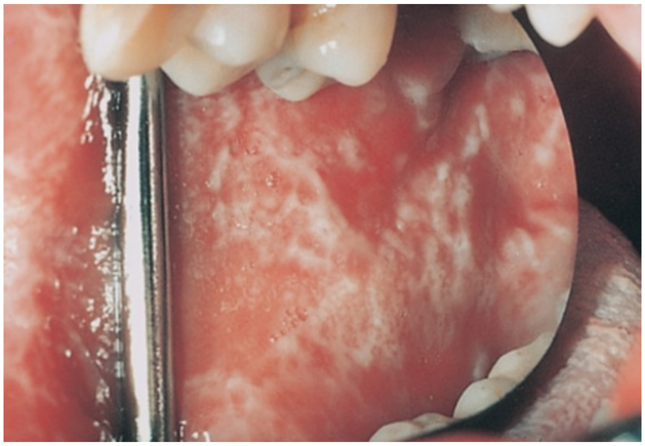

Figure 84.13 Lichenoid lesions of oral cGVHD showing crythema, white striae, plaque, and ulcer formation, day 394.

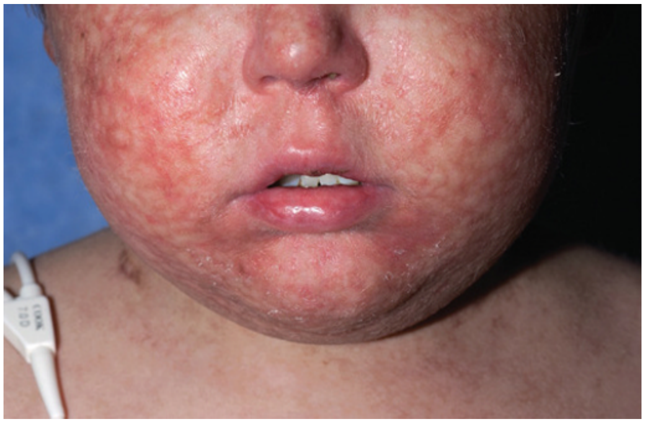

Figure 84.14 Decreased oral range of motion and microstomia in a patient with sclerotic features of cGVHD. This is a diagnostic manifestation. Note the erythema, edema, and atrophy of the vermillion lip and labial mucosa.

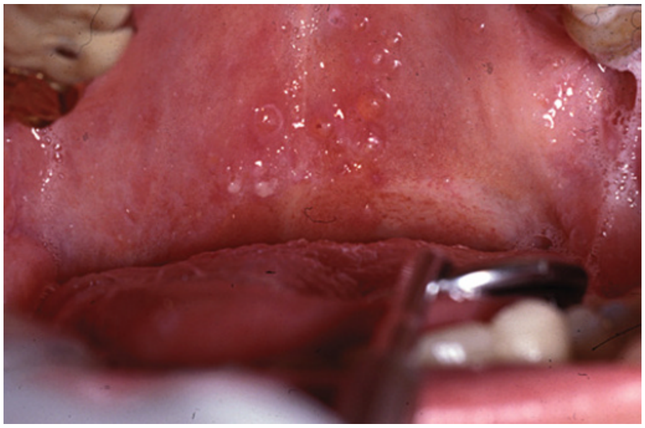

Figure 84.15 Numerous vesicle-like mucoceles (a distinct manifestation of cGVHD) are seen along the center of the soft palate. Patchy white lichenoid hyperkeratosis (diagnostic of cGVHD) and interspersed moderate erythematous changes are also evident across the soft palate. Additionally, note the foamy mucus saliva consistent with GVHD salivary gland dysfunction.

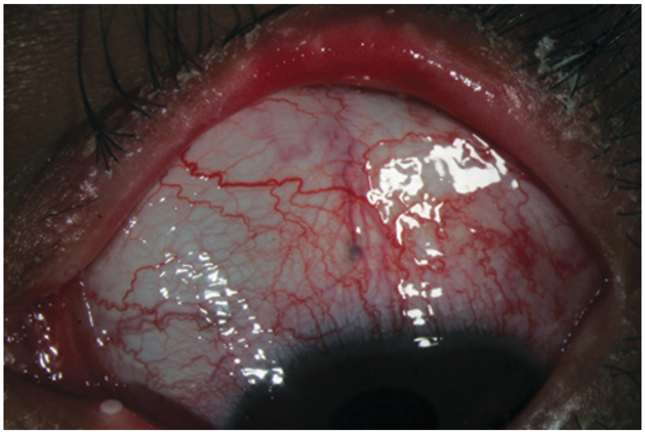

Figure 84.16 Keratoconjunctivitis sicca with blepharitis. The eyelid margins are thickened, edematous, and erythematous. Also note plugging of the meibomian gland orifices (along the eyelid margin) and significant conjunctival hyperemia/injection. A punctal plug can be seen at the lower left margin of the image.

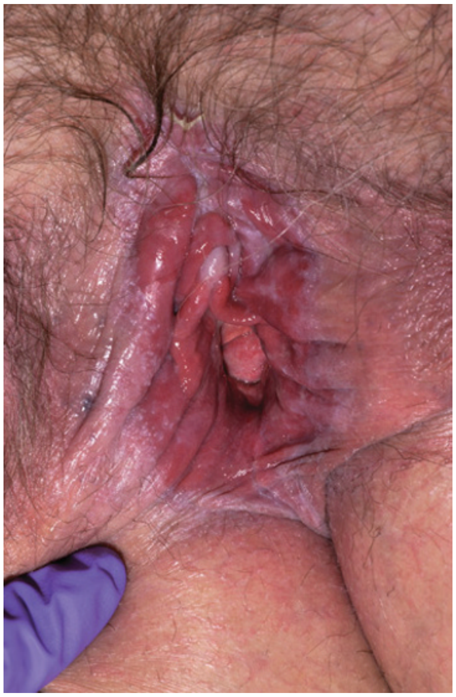

Figure 84.17 cGVHD involving the vulvovaginal tissues. Note lichen planus-like manifestations, which are diagnostic of cGVHD. Also seen are erythema and agglutination of the labial tissues.

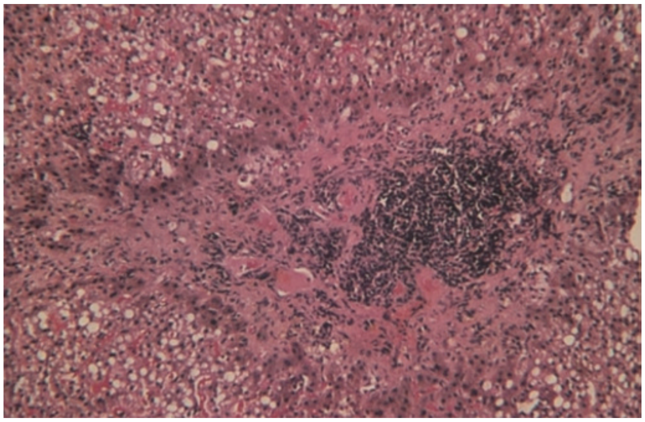

Figure 84.18 cGVHD of the liver, day 166. This biopsy shows a prominent plasmacytic infiltrate in the portal area and a paucity of interlobular bile ducts. The histological dichotomy between acute GVHD and cGVHD is less clear in the liver than in skin. However, increased portal inflammation and loss of bile ducts are more common in cGVHD. Despite the frequency of chronic hepatic GVHD, cirrhosis and liver failure are rare and may reflect superinfection with hepatitis C virus. (See also Chapter 23.)

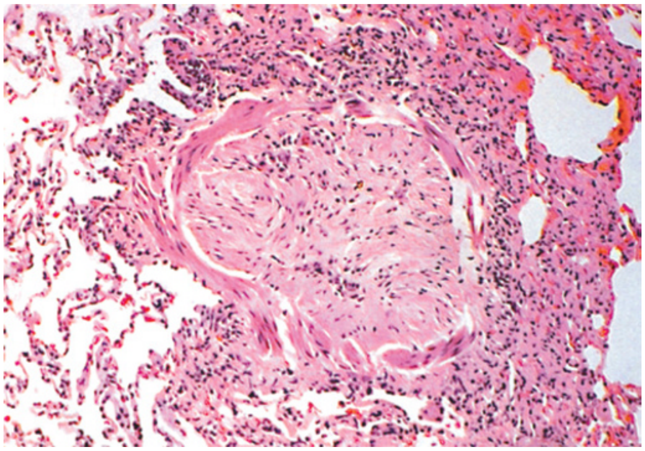

Figure 84.19 Bronchiolitis obliterans in a lung biopsy, day 396. The patient had cGVHD with severe obstructive pulmonary disease. Similar small airway inflammation with fibrosis is seen in lung allograft rejection. (See also Chapter 23 and Chapter 47.)

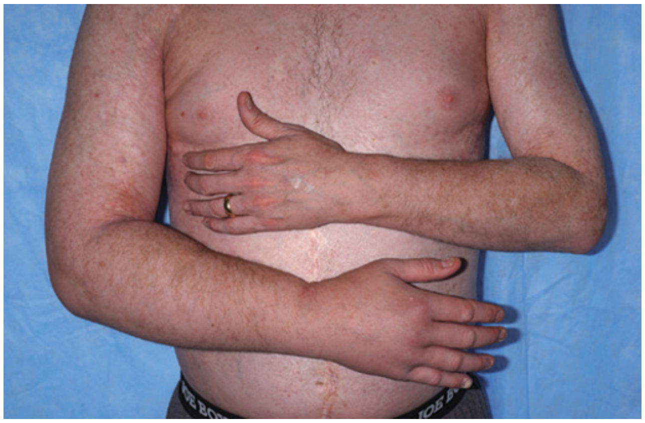

Figure 84.20 Edema in the extremities can be bilateral or, as shown, unilateral. Edema may be an early sign of evolving subcutaneous sclerosis and fasciitis.

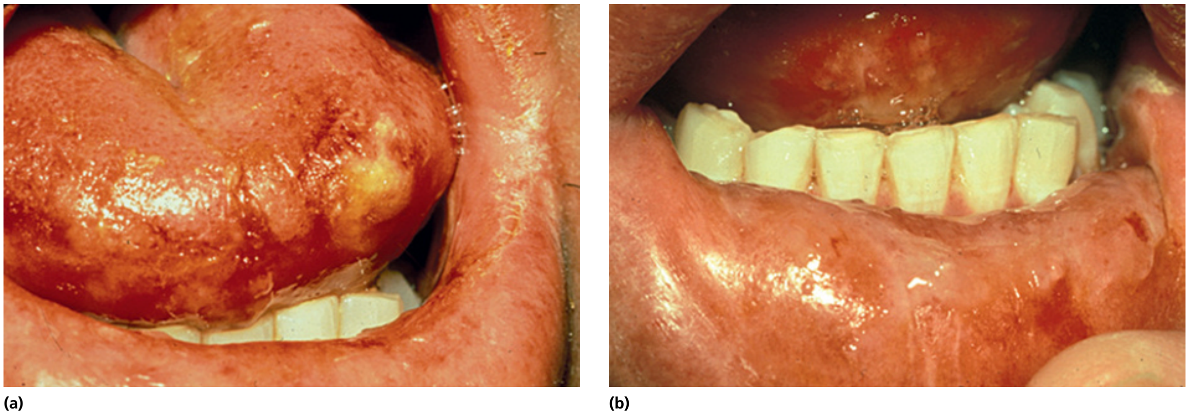
OLD
RLD
(d) Chronic Interstitial Pneumonitis
(e) Restrictive Interstitial Fibrosis (RLD)
Phase one
Phase two
Phase three

Figure 95.5 A triphasic model of OLD and RLD following allogeneic HCT. Immune-mediated injury to the lung after allogeneic SCT can be conceptualized in three phases. In phase one, acute lung injury develops as a consequence of an allogeneic immune response and results in the sequential influx of lymphocytes, macrophages and neutrophils into an inflamed pulmonary parenchyma (a). Persistence of an inflammatory signal in the setting of dysregulated repair mechanisms promotes the transition from acute to chronic injury in phase two (b and d). As chronic inflammation proceeds to phase three, lung fibroblasts increase dramatically in number and contribute to the enhanced deposition of collagen and granulation tissue in and around bronchial structures, ultimately resulting in complete obliteration of small airways and fixed OLD (c). If, by contrast, the principal target of early damage is the alveolar epithelium, fibroblast proliferation and intraseptal collagen deposition ultimately result in interstitial fibrosis and RLD (e).



(a) (b)

Figure 101.2 Severe oral mucositis occurring 8 days after hematopoietic cell transplantation following conditioning with VP-16, cyclophosphamide, and total body irradiation (World Health Organization mucositis score of 4). Bleeding ulcerations are noted on the anterior ventral area of the tongue (a) in this patient, with simultaneous pseudomembranous fibrin exudate-covered ulcers evident on the lower labial mucosa (b).

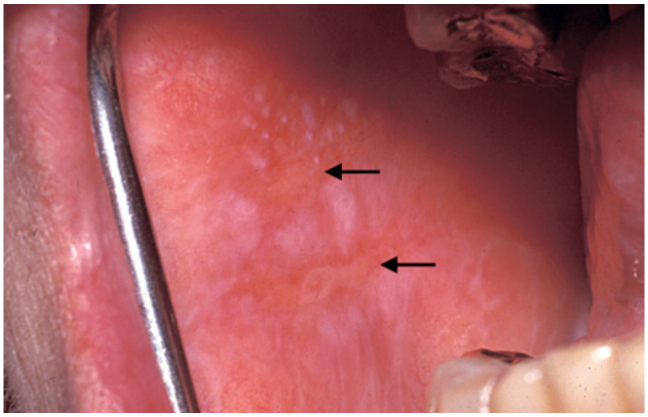


Figure 101.3 Oral chronic graft-versus-host disease in a patient 1 year post-HCT, with lichenoid hyperkeratotic changes (stria-, papule-, and plaque-like changes) associated with generalized atrophic and erythematous mucosal changes involving the right buccal mucosa. Small initial pseudomembranous fibrin exudate-covered ulcers are indicated by arrows.

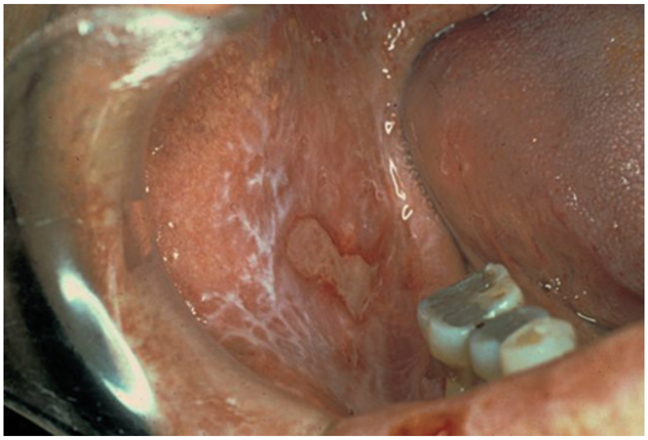

Figure 101.4 Severe oral chronic graft-versus-host disease showing distinct hyperkeratotic lichenoid striae and a pseudomembranous fibrin exudatecovered ulceration with intense surrounding inflammation in a patient approximately 18 months post-HCT.

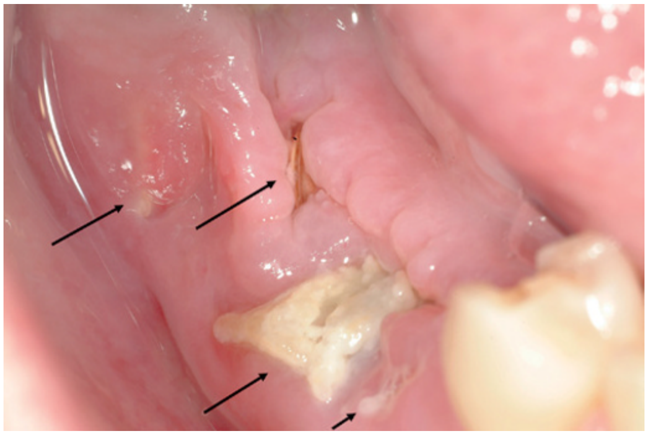

Figure 101.5 A 45-year-old male with a history of multiple myeloma who had been treated with intravenous zoledronate for 2 years prior to having two lower right molars extracted. He presented with three areas of bisphosphonate-associated osteonecrosis of the lower right mandible 6 months following the extractions. Lesions were non-painful and stable. Arrows indicate areas of bone exposure.

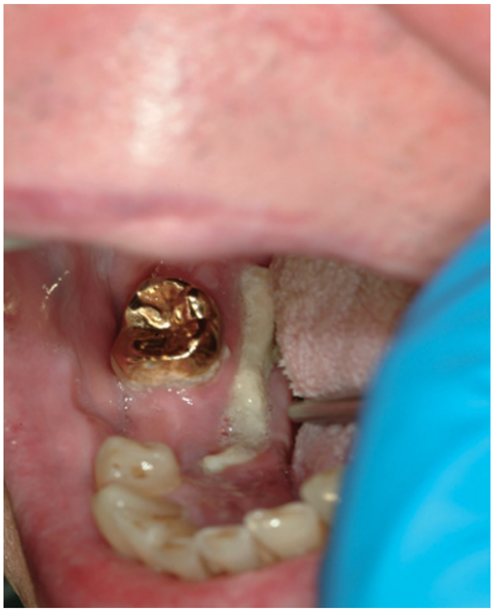

Figure 101.6 Bisphosphonate-associated osteonecrosis of the jaw involving the lower right lingual ridge in a patient with multiple myeloma treated with intravenous zoledronate monthly for 20 months. The patient's second bicuspid and first molar had been extracted 3 months earlier due to what was thought to be severe peridontal disease; the primary extraction site healed, but an extensive area of osteonecrosis developed along the mandibular lingual torus that was present lingual to the original extraction site.

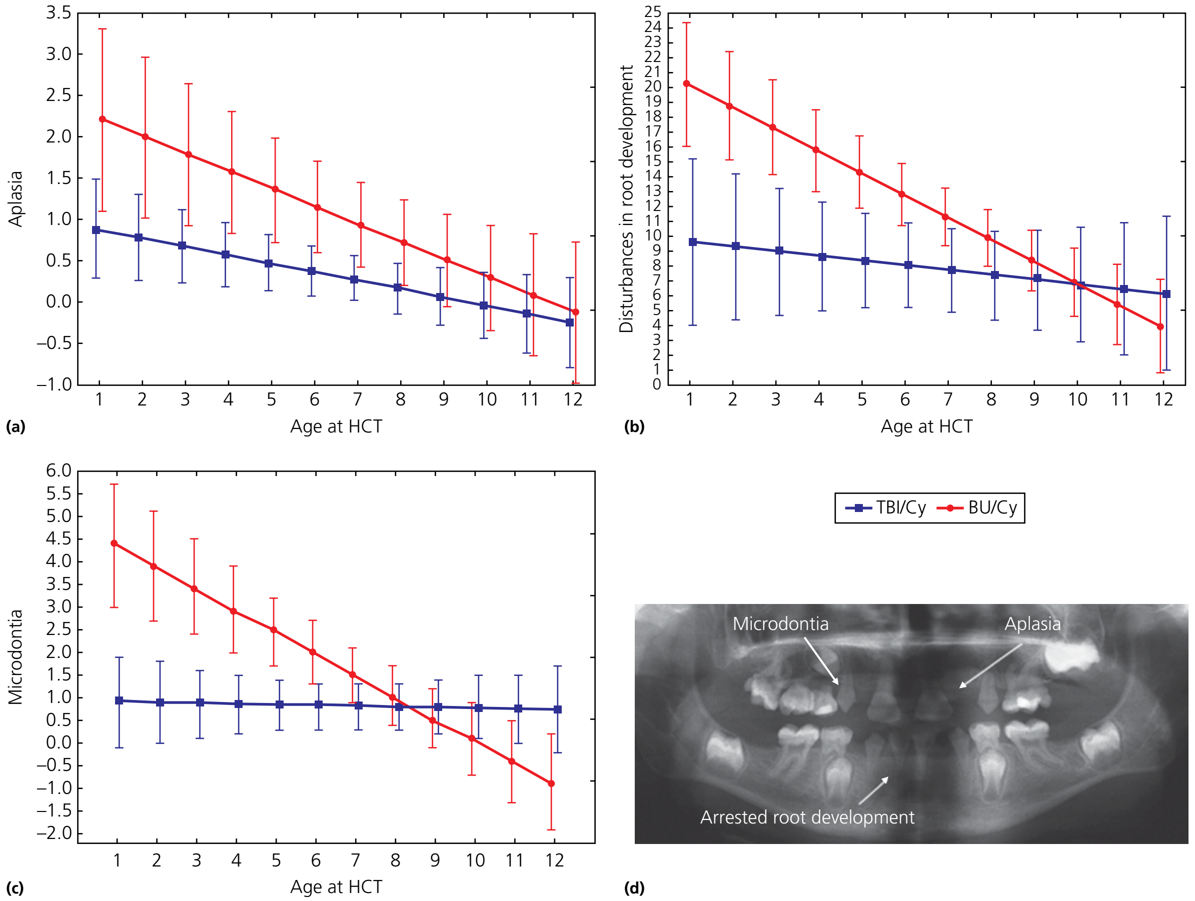

FIGURE 101.7 Disturbances in dental growth and development in long-term survivors of HCT. Conditioning regimes for HCT can cause severe disturbances in dental growth and development for pediatric HCT patients with TBI-containing regimes causing more problems than chemotherapy-only regimes. The younger the age at the time of transplant, the more significant the disturbance in dental developmental. (a) Number of missing teeth in children subjected to HCT by age. (b) Number of teeth with disturbances in root development by age. (c) Number of teeth with microdontia by age. (d) Panoramic radiograph showing arrested root development, microdontia, and aplasia of teeth in a pediatric long-term survivor post-HCT. Source: reproduced with permission of G. Dahllöf, K. Garming Legert, M. Remberger, and O. Ringdén Support Care Cancer (2012) 20 (Suppl 1):S226; 945.
